An American Photographic Dinner.—Mr. Henry J. Newton presided at the annual dinner of the Photographic Section of the American Institute a few weeks ago. Proposing a toast, he invited all who liked cold water to drink it. He did not exactly know the programme of the evening, as the Chairman of the Committee was at the other end of the table, and he (Mr. Newton) could not see him without an opera-glass! It must have been a large party. Then, after a joke or two, the President asked for information about orthochromatic plates. Dr. A. H. Elliott obliged in a speech of about a column and a quarter, and Dr. C. H. Ehrmann followed suit in an oration of double that length. The report of the dinner, according to *Anthony's Bulletin*, in which it appeared, was "to be continued." The President, at the outset, supposed "the speeches would be dry." They were. Fancy, about four columns and a half of the orthochromatic process at an English photographic dinner! Alas, it is occasionally something more than fancy; it is grim fact! Hence we can compassionate our American brethren who had to sit under the four-and-a-half columns.

FOREIGN PHOTOGRAPHIC INSTITUTIONS AND THEIR INFLUENCE.

[London and]Provincial Photographic Association.]

THE original intention in relation to this paper was to make it heavier, by the introduction of statistics and by entering into more minute details about foreign photographic institutions, but exceptional pressure of other engagements during the past two weeks left me no time to search out the necessary documents for reference. I should have liked the postponement of its reading, but felt that that course would disturb your arrangements, especially as Mr. Warnerke had set apart this evening to bring here an interesting collection of lantern slides bearing upon the subject. Perhaps, after all, the colloquial narrative about to be given in relation to foreign institutions I have visited, may be less tiring to the listeners than if the paper were of a heavier nature.

Recently Mr. Warnerke gave the Photographic Society a valuable memoir upon practically the same subject, and spoke only of what he had seen himself. The present paper may be considered an unauthorised appendix to his, and, if others acquainted with Continental photographic institutions will hereafter contribute their share of information, a body of facts will have been collected which seems to be publicly required at the present time.

BELGIAN PHOTOGRAPHIC SOCIETIES.

The nearest foreign country to England in which there is much photographic activity within easy distance of London is Belgium, a nation known for holiday-making to many here present, several of whom, however, have not given attention to its photographic societies, or rather to its photographic association, for, practically speaking, it has but one, all the branches of which are federated. This system has worked well for a long course of years. The head of the Association is Mr. J. Maes, of Antwerp; its headquarters are in Brussels, and its Secretary General is Mr. Charles Puttemans. Mr. Maes is the chief photo-mechanical printer in Belgium, and for printing he uses French and German machines. He is also President of the Antwerp section of the Association. Mr. A. de Blochouse is President of the Brussels section; he is a retired engineering photographer, and one of the most popular men connected with photography in Belgium. Some years ago I was much indebted to him for information about the state of photography in his country. The Ghent section is under the presidency of Professor De Vylder. The Liège section is under the presidency of Mr. Raoult, and holds its meetings in the University, in the scientific department of which it is surrounded by all the facilities for research which the photographic mind could desire. On inspecting its domicile, I wished that we had something in any degree approaching it at home. One result of the general union of Belgian societies is, that the Association has but one journal to serve all, so that, with this concentration of effort, the *Bulletin Belge* is one of the best photographic journals in the world, and it received a special award on that account at the last Paris Exhibition. Captain Abney once contributed to its columns with considerable regularity. No personal disputes or particulars of dissensions find a place in its pages, and the chief photographic journals of the world are carefully searched every week for any items of novelty, brief summaries of which are printed regularly at the end of the *Bulletin*. It is scientific in its tone, and adapted to the requirements of the scientific mind; but, then, it must be remembered that the average education of the Belgian people is high. Boys and girls, even in agricultural villages, are commonly enough taught three living languages, and pretty well taught too, as I know from conversations with some of the children. At Ghent, photography in some of its more difficult branches is taught to the chemical students in the University by Professor Donny; for instance, he teaches them how to produce ceramic photographs. He is a photographer of long standing, for a letter from him on the subject is to be found in the first volume of our Photographic Society. Ghent claims the honour of being the city which first began to put into practice the free-education system which so long since has spread over a considerable portion of Continental Europe. Its inhabitants, it may perhaps here be mentioned, have a great love of flowers, and

its floriculturists spare no expense in obtaining the rarest flora curiosities.

Quite recently I spoke at the Photographic Society about the Government School of Photography at Brussels; how it gives long courses of lectures on photography free, and provides for serious students the free use of costly instruments for photographic research, so that it is unnecessary to say more upon that subject here.

A short distance south of Brussels is the Military Map Department of the Belgian Government, in which photo-mechanical processes are extensively used.

The next meeting of the International Photographic Congress will be held at Antwerp, a most convenient place to reach from London. Having tried all of them, I prefer the Harwich route, which is far different from what it was in the days of old. Should British photographers visiting Belgium wish to inspect its photographic institutions, if they meet the same kindness there which I have received, they will have no reason for complaint.

French Photographic Societies.

Turn we now to

"The land of France,
The chosen home of chivalry, the garden of romance."

The Photographic Society of France meets once a month upon premises of its own, 76, Rue des Petits Champs, Paris. The salon in which its public meetings are held has a rich collection upon its walls of photographs of high historical value, and it is meet that such should be the case in the country of the chief founder of photography, Niépce de Châlons; also the country of Daguerre. In the collection are several beautiful photographs in pigments by Ducos du Hauron by the ingenious process which has been so often reinvented, sometimes with modifications or improvements, in this and other countries. Its president is Dr. Janssen. This Society is not parochial in its work, and believes that something good in photography may be done out of France, consequently a summary of anything new in photography appearing in any foreign journals is briefly brought under the notice of the next meeting. There is a moderate amount of formality in the proceedings at the meetings, but not more perhaps than is necessary to secure expedition in doing the work. This Society took an active part in founding the International Photographic Congress, which was but one of, say, thirty or fifty International Congresses held at Paris during the last Exhibition there, when all the world and his wife were in the gay capital; consequently the time and place were as convenient as any which could have been found, and I think that the members of most scientific bodies were thankful that the Parisians brought them together by means of those Congresses. The *Bulletin* of the Société Française de Photographie is carried on upon strictly scientific lines, and is rich in contributions of permanent historical value.

I have also visited the photographic societies of Nantes, Havre, and Douai, all of them chiefly composed of amateurs. At Douai the society holds its meetings, and has rooms, in the Museum. A portion of the building is devoted to chemistry and physicul science; so this Society has all facilities for demonstrations and research. It is an interesting Society, and has some unique literary and pictorial records of its own, contributed by men of exceptional ability. It writes and lithographs its own journal, as also does the Photographic Society of Versailles. A man whose handwriting is clearly legible copies that which is selected for publication, and the pages are printed off in the lithographic press.

A few weeks back a letter appeared in the photographic press from a resident in Havre, to the effect that he had a dark room for the use of strangers. That is all very well; but, judging by recent occurrences in France, what is likely to be the fate of any photographer who takes pictures in the great shipping port of France, with its adjacent fortifications? I once put this question to some members of the Havre Photographic Society, who said that they "thought" that any foreigner might photograph inside the town, but they would make inquiries and let me know later on by post. That information never came. In many parts of Havre the heights behind the town form the background to the street scenes, and, if guns chance to be upon those heights, what will be the fate of those innocent strangers who venture to take snap-shots in the street with a camera? In places not near the frontier the Germans would simply bully such strangers, and tell them to be off; but the results of doing the same thing in France would be more prolonged and more unpleasant especially in small places in which the local magnate has a concentrated sense of his own dignity. If these small gentry be not spoken to with abject humility, they will swell up like Mr. Maskell's cat. Officialism is overdone in France; among the higher officials are plenty of thorough gentlemen, and among the lower are some—but a few in number, I hope—who are the reverse.

The Photographic Society of Havre has a nice building of its own in the eastern part of the town; the members I have met gave me every cause to remember the meeting with pleasure. An exhibition of the work of the members was going at the time, and attracted great numbers of the townspeople to an extent beyond the anticipations of the Society.

At Lille, in the Hall of the Sugars, is an interesting collection of early photographs and photographic objects of interest. In another public institution in the town, as I have been informed by Mr. William England, are two old pictures, not photographs, proving that the way to produce stereoscopic effects was known long before the time of the supposed modern invention. On two occasions, when in Lille, I tried, without success, to discover the whereabouts of these pictures, not possessing the name of the place in which they were kept. Some changes were being made in the art galleries of Lille at the time, which may account for my not finding them. In past times I have now and then seen notices of them in books, but forgot where.

The Nantes Society publishes its own proceedings. The country between Tours and Nantes well deserves the attention of photographic tourists—especially the towns of Chinon and Angers, with their magnificent old castles. From the neighbourhood of Angers came the Plantagenets. This region is the garden of France.

Photography in Switzerland.

In Switzerland the head-quarters of photography are at Geneva The *Revue Suisse* is published there, and the Photographic Society of Geneva flourishes in the city. In the autumn of 1890 it held an excellent exhibition, and some large heads by the carbon process, exhibited by A. Ruffo, Prince de la Scaletta, of Rome, were unique, so far as my experience goes, which, in comparison with the experience of some of those I see around me, does not count for much. They have an indescribable, but distinct, character of their own, a character as well marked out from the ordinary run of photographs as have those of Mrs. Cameron. M. Nerdinger is the president of the Geneva Photographic Society. The Swiss photographic societies are united somewhat in the same manner as the Belgian societies, in the matter of the publication of their proceedings in one journal, the *Revue Suisse*.

The well-known photographer, Mr. Pricam, of Geneva, is the president of the Swiss Photographic Society, an organization dealing with the commercial interests of Swiss professional photographers. I do not think that they could have found a better man for the position. He was one of the photographic jury at the Paris Exhibition, and he attended the last Brussels Congress. Mr. Warnerke has his likeness.

During a few hours' stay in Neuchâtel I was unable to find any of the officers of the society; they were mostly university men and in vacation at the time. At Lausanne I had no time to make the attempt so to do.

We come now to Zürich, the chief commercial city in Switzerland. The Polytechnic School there is known by reputation or otherwise throughout the world to those persons who are interested in the subject of national education. Its students have to take a three years' course of instruction at the cost of four pounds a year, for which they may be taught chemistry, civil engineering, railway engineering, architecture, or some one or other of the learned professions. The candidates for admission must be able to pass what in Switzerland is considered an elementary examination; they must have a knowledge of mathematics, and of two living languages in addition to their own The benefits of this institution are not confined to the Swiss people who keep it up, for students from any part of the world are received upon the same terms. Altogether during my visit to visit to Zürich I spent much time in the establishment collecting information about it, and chiefly from Dr. Georg Lunge, one of the best of living chemists, and a noted authority upon alkali manufacture. He knows England well; in fact, he lived in this country for several years.

At the time of my stay in Zürich there was no photographic society in the city, but one has been established there since. At the Polytechnic School was a developing room for the general use of students.

In Italy photographic Societies are of recent date. There are but few in the whole nation, and the first one was established at Florence about six or eight years ago, as the outcome of a successful photographic exhibition in that city. I have not chanced to be in any Italian town at the same time that it possessed a photographic society At Turin is an excellent Photographic Club, which prints a good journal of its own.

Influence of Foreign Photographic Institutions.

The influence which foreign photographic and other educational institutions exert in these days of commercial competition seems plain enough. Suppose a young Englishman, possessing the average education given to the bulk of the people in this country, and the averag

knowledge of photography learnt under the teaching of an average professional photographer, to go "out West" in the United States, and to settle down in some new town, in which he has but one competitor, a young Belgian. The latter we assume to have been taught three living languages, to have been taught, not alone practical photography, but its underlying laws and principles, to have been taught optics and chemistry, the use of high-class instruments for photographic research, to have been trained in drawing and painting, and all this at remarkably small expense. In Ghent, for instance, which is not a particularly large place, he has every facility provided for inexpensively acquiring all the knowledge just stated. Suppose all other conditions of the two individuals but those just stated to be equal, which is likely to become the victor in the race of life? The Belgian, say I. In modern civilised society, education takes the place which weapons and physical strength take among savages. In these days the properly educated man is the strong man armed, and that, too, with a weapon which cannot be taken from him, whilst his uneducated brother is more likely to be a sheep to be shorn. A man who growls about the cost of general education is like a savage who tries to make other savages go unarmed, because of the expense in money or labour of acquiring weapons. Mr. H. M. Elder has told us how certain English photographic firms have been obliged to send to Germany for some of their best men; I have seen photo-mechanical work for London customers in the act of being printed in Germany, and I know of one great photographic firm in London now employing some of Goupil's former men, because of their practical skill. Too large a proportion of useful photographic novelties comes from abroad. The plodding, heavy kind of tradesman says to the inquirer: "I do not keep such-and-such a thing; there is no demand for it." Yet the thing may be obviously useful, and it is not the business of the public to go down on its knees to home dealers to supply useful things they will not otherwise keep; it is simpler to go to a dealer in foreign goods, when he chances to have something meritoriously useful, which he introduces in the hope that the public will recognise its value. Much more might be said on this part of the subject, but at this hour what has been said is sufficient to start a discussion.

"You have no personal practical knowledge of the action of these commercial influences in photography," says—or ought to say—an objector. That is true, so upon this branch of my subject I come here as much to be taught as to teach; therefore, will now sit down in this chair, preparatory to being sat upon by you after our chairman has exhibited his interesting lantern slides. As you are just, so be merciful.

W. H. Harrison.

PHOTOGRAPHY AND PHOTO-MECHANICAL PRINTING.

I.

[Two Lectures delivered before the Officers of the Royal Engineers at the Military School, Chatham.]

For the purposes of my paper on photo-mechanical printing processes it is not necessary for me to go very deeply into matters connected with the discovery and general history of photography, neither will it be necessary for me to attempt to go into detail on the elaborate chemical changes which occur in the processes I shall describe, and by the study of which, step by step, the present exact knowledge has been attained of the wonderful action of light on various organic salts. It will be sufficient for my present purpose if I give you a short *résumé* of the first researches made as to the chemical action of light on some of the substances employed in photography, briefly explaining as I go along what these chemical changes are and their effect, so that you will better understand the phenomena of the experiments I shall show you. For details of the photo-mechanical printing processes I shall introduce to you I cannot do better than advise you to study one or other of the special text books published on the subject. Those amongst you who desire to make a scientific study of the art will do well to obtain the excellent works of Hardwich & Dawson, Captain Abney, R.E., W. K. Burton, and others, whose researches into the cause and effect of light action have been most exhausting and most interesting.

Action of Light on Silver Salts.

I suppose you all know, except the little boy in the corner, for whom my paper is intended as well as your scientific selves, that the word photography means literally *writing by means of light*, and it includes all processes by which any kind of a picture may be obtained by the chemical agency of light. The ancients knew hardly anything about the subject except, perhaps, that a substance which they called "horn of silver" blackened when exposed to light. In 1777 a clever Swedish chemist called Scheele made some researches as to the decomposing action of light on compounds of silver, and he found that this decomposing action was greatest in the violet end of the spectrum; he also attributed the blackening of chloride of silver to the liberation of chlorine and the formation of hydrochloric acid, which theories were quite correct, but very little notice was taken of the discoveries at the time, they were looked upon as mere curiosities. About thirty years later, in 1802 Wedgwood and Davy attempted to utilise silver salts for picture-making purposes, and, curiously enough, they practically employed the very methods in use to-day in their experiments. They soaked sheets of paper in nitrate of silver, and projected a shadow of the object they wished to copy upon it. The parts of the paper upon which the shadow fell remained white, whilst the parts exposed to the sun's rays gradually turned dark, the result being a negative image of the object shadowed or photographed.

Here is a piece of paper treated as above, showing approximately the effect of Wedgwood and Davy's researches. Up to this time, however, and for perhaps thirty years later, no method of fixing these light pictures was discovered; consequently, they could only be examined in a dull light, and, unless kept in the dark, soon disappeared altogether. In 1821 Herschell announced that hyposulphite of soda would dissolve the haloid salts of silver, but the fact seems to have been overlooked until Fox-Talbot's investigations brought the matter to a practical application in 1839 in his Talbotype process. Talbot made great advances in photographic science, and found how to make pictures in the camera, the images of which were invisible when made, but were capable of development afterwards. Contemporaneously with the experiments of the Englishmen named, Daguerre and Niépce in France were making successful researches into photographic picture-making, one by the well-known and beautiful process bearing the name of Daguerreotype, the basis of which was a plate of silver, having upon its surface a thin film of iodine, which substance, combining with the metallic silver of the plate, produced Iodide of silver (a salt highly sensitive to light). The plate thus prepared was exposed in the camera, and the image obtained, though invisible at this stage, appeared on the plate on its being submitted to the fumes of mercury. This production of a latent image capable of development was of the first importance, as it reduced the exposure in the camera from hours to minutes, and, in conjunction with Fox Talbot's process, opened the door to a whole range of discoveries, the mere naming of which would occupy the whole time at my disposal this evening.

Mr. Fox-Talbot was the first experimentalist who succeeded in making what is technically known as a negative, and in 1850 Mr. Archer discovered our present collodion process for making negatives.

Collodion is a thin, syrupy solution of pyroxyline or gun cotton, dissolved in ether and alcohol, and it is used as a vehicle to carry the haloid salts of silver on the glass negative. We will dissolve a little cotton in ether and alcohol to show you how rapidly the prepared vegetable fibres are dissolved by the solvents. To this solution is added bromide and Iodide salts, and it is then poured over a glass plate, and the plate is dipped for a few minutes into a bath containing about thirty-five grains of nitrate of silver to each ounce of water. The silver in the water combines with the bromides and Iodides in the collodion, and forms double salts which are sensitive to light. The plate in this state is ready for exposure in the camera, and is what is generally known as the "wet-plate" or "collodion" process, in contradistinction to the now better-known gelatine or dry plate.

A negative is a transparent picture having the lights and shades reversed. Here is a negative, and you see that those parts corresponding to the dark portion of the original are transparent, whereas those parts which correspond to the lights of the original are opaque. Here, on the other hand, is a positive or transparency of the same subject as the negative which you have just seen, the lights and shades of this being the same as the object represented. A negative from nature should show the reverse of all those gradations of light and shade which characterise natural objects, while a negative taken from a line engraving should show only two gradations, complete opacity and clear transparency. Here is such a negative as is in use for all classes of photo-mechanical processes in line.

The Bichromate Processes.

The discovery by Mungo Ponton in 1839 that bichromate of potash could be used for making paper sensitive to light was of immediate importance. There is scarcely a photo-mechanical process in existence which is not more or less dependent on the action of one or other of the bichromates in combination with an organic substance, such as albumen, gelatine, and starch.

Were it not for the curious action light exerts on organic substances charged with a small proportion of bichromate, a whole range of beautiful

processes now in every-day use would be impossible. Pigment printing by means of the carbon process, photo-lithography, photo-zincography, photo-etching and engraving, Woodburytype, collotype, and a host of lesser processes, are one and all entirely based on the effects imparted by salts of chromium to organic matters, such, for instance, as gum, glue, gelatine, isinglass, starch, dextrine, &c. To explain to you the action of light on any one of these substances when treated with bichromate, we have prepared some sheets of paper with a coating of ordinary gelatine. This sheet of gelatine paper has not been treated with bichromate, and it can be exposed to light indefinitely without affecting its nature. This sheet has acquired the property of becoming sensitive to light by being soaked for a few minutes in a three per cent. solution of bichromate of potassium in water, and dried. The light acts in two definite ways on bichromated gelatine prepared as described, first, by rendering it insoluble; second, by causing it to lose its property of absorbing water or swelling; and these peculiar properties are seized upon by the scientific photographer, and utilised by him in the making of many wonderful picture-producing surfaces. Now, this piece of bichromatised gelatine paper has been exposed to daylight under this negative for five minutes this afternoon, and if you examine it you will find a faint image of the lines of the picture. If I dip the piece of paper in water, and let it soak a few moments, a marked effect is produced. The unused bichromate in the paper dissolves out into the water, and the unacted upon gelatine swells, but the parts represented by the clear lines of the negative, and oxidised by light, remain unswollen, non-absorbent, and sunk; that is to say, if this piece of paper were laid on a flat surface, and plaster of Paris poured upon it, we should get a cast in relief showing every line of the original drawing, from which, by recasting in metal, we might obtain, by this means alone, a stereotype plate for printing with type. Many excellent processes for type-block making are worked on this principle. Now, another valuable property of this same gelatine, when sensitised and printed, is its affinity for taking greasy ink where light has acted, and refusing to take ink where light has not acted. Sapper Royall will take a printing roller charged with ink, and coat a similar piece of exposed gelatine paper with ink all over—when dry, it can be inked all over—and Mr. Geddes will afterwards soak the paper in water, when you will observe that with a slight rubbing the ink will leave the gelatined paper everywhere, except on the parts acted upon by light.

The inked photograph of the lines of the negative on gelatine paper, made in the way shown to you, is technically called a "transfer," because it is used for the purpose of transferring the ink on its surface to a lithographic stone or a grained zinc plate, from which base the image or lines thus transferred can be further inked and strengthened, after which treatment the stone or plate is placed in an ordinary lithographic printing press, and any number of copies printed in the usual manner. When I say "usual manner," I am presuming that you understand generally what ordinary lithographic printing is, and that you have also some idea of its principles. Perhaps, after all, it would be safer if I do not "presume" anything (in case any of you have forgotten), and I will just run over very briefly the manipulations of simple lithographic printing. (To describe it properly would involve a paper thrice the length of the present one.)

Lithographic Printing.

Solenhofen slate is a porous limestone which has obtained the name of lithographic stone from its capability of being used as a printing surface, from which an indefinite number of copies of any drawing or transferred picture can be taken. This stone is polished smooth and level for use, and it possesses the property of greedily absorbing both greasy ink and water; if a drawing is made upon it with an ink made of grease and lampblack dissolved in soap, the grease sinks into the stone, and each line so drawn forms a permanent printing surface, which will "take" more ink from an inked roller, and then give up a portion of the ink to a sheet of paper pressed in contact with the face of the stone. To prevent the stone inking all over when using a roller, the stone is damped before rolling up with a sponge and water; the stone absorbs water everywhere except where the lines occur, which, being greasy, repel water. You see, therefore, that the principle of lithographic printing is simply employing a surface which "takes" ink, and ink only where there is already ink, and water, and water only where there is already water.

Here is a lithographic stone on which a drawing has been made, also a similar stone upon which a photo-lithographic transfer has been impressed, as well as proof from both stones. You will observe that there is practically no difference in the results, one subject being laboriously drawn by hand line by line, and the other the result of photographing a print or a drawing which has been much more easily obtained.

I will now take another similar sheet of transfer paper which has been already washed and inked up, and will pass it through the transfer press so that you may see the exact method of treating these transfers. I, however, will not use a stone, but a sheet of zinc, which possesses the same properties as lithographic stone, but is more convenient for the purpose this evening. You will see that the ink leaves the gelatine surface of the paper, and attaches itself to the metal or stone. If the transfer is successful, we will pull a few copies to show the complete process.

I mentioned in the historical notes that Niépce had discovered the fact that bitumen or ordinary asphalt was sensitive to light. As I still have some time, I will make a short *résumé* of this process.

The process is extremely simple, ordinary bitumen or asphalt is dissolved in benzol, and a metal plate is covered with a thin varnish of the substance.

Niépce employed this method for the purpose of making pictures on glass, but we use the bitumen now entirely for obtaining an acid-resisting image on metal for etching or engraving purposes.

Here is one of these plates ready for use. Exposure to light has the effect of rendering the bitumen varnish insoluble in certain essential oils in which, previous to its exposure to light, it was quite soluble. This singular property is utilised in our modern processes for producing the delicate images on metal of drawings in line, which are afterwards etched by acids either for typographic blocks or intaglio plates. The plate which I handed round to you just now has been exposed to the action of light under a negative of a line drawing, and, though there is no image visible, I will now show you the effect of a little common turpentine over a portion of the plate. Here is the drawing and the negative made from it, under which the plate has been exposed. You see that the turpentine at once dissolves and removes the portion of bitumen which were protected from light by the negative, but it has no effect upon the parts acted on by light, and represented by the clear portion of the negative and by corresponding lines on the metal plate. To-morrow I shall have the pleasure of describing to you how by etching such a plate as Niépce's, we can convert it into a block for printing with type in a printing press.

Niépce's discovery, about the year 1825, of the curious effect of light on bitumen is very interesting from the fact that the process, only slightly modified, is employed to-day for the production of some of our finest photo-etched plates. I believe there are in the British Museum some specimens of Niépce's bitumen plates showing his attempts at etching quite half a century before there was any practical use made of them.

One of the most beautiful processes, namely, photogravure, was largely dependent in its beginning upon this action of light on bitumen.

Photogravure.

Photo-intaglio engraving is, as its name implies, just the opposite in effect to the photo-relief blocks, which I shall describe to-morrow evening, the principles are the same, however, and the difference in result is obtained by using a positive or transparency for obtaining the pictures on metal (instead of a negative), and by etching away the lines themselves instead of the metal surrounding them. I have here a copper plate with the picture on the metal printed from a positive, and a plate upon which a similar picture has been etched, so that you can see at a glance how the results are attained.

The simplest way of obtaining a photogravure plate of a line subject is to coat a piece of copper with a thin solution of bitumen in benzol, and expose this plate under a clear, sharp transparency in a printing frame. The exposure will take about an hour in a good light. After exposure the image is developed with a little turpentine, and on the dissolving away of the unacted upon parts represented by the lines on the transparency, the picture will appear as bare metal on a ground of bitumen varnish. On applying an etching solution of perchloride of iron to the surface of such a plate, the etching solution at once attacks the portions of metal bared by the developer, and quickly bites out the lines to a sufficient depth to permit of the plate being inked in and printed from. If the subject required is in gradations of tone, like a portrait or a landscape photographed from nature, then a different treatment is necessary, and the following method is perhaps the best. From the transparency, or positive, of the tone negative a print is made in carbon, exactly in the same manner as if one were making an ordinary print; but, instead of developing the carbon print on paper, it is developed direct on to a copper plate, which has previously had a fine grain of resin deposited and melted upon it. A grain of some kind is necessary on all half-tone photogravures, because without it there would not be sufficient texture in the etched pictures to hold the quantity of ink necessary to give a vigorous print. After the carbon print of the transparency is developed and dry, it should present the appearance of the plate which I handed round to you, and it is ready for the etching fluid, which is again perchloride of iron. A little practice is necessary in order to determine the right

strength of the etching solution, as well as to judge properly the exact moment when to stop the operation of etching, because, if the solution is too strong, it will only etch the deepest shadows, and if it is too weak it will etch too quickly all over the surface, and give a flat, thin picture. Here is a plate which is fairly well etched, together with some proofs. The plate, you will observe, is steel faced, which is always advisable; the hard facing protects the delicate details from being too rapidly worn away in the printing.

PAUL L. WATERLOW.

STEREOSCOPIC PHOTOGRAPHY.—A REPLY TO MR. J. C. ANNAN.

PROMPTED by a desire to introduce a discussion, viz., "to inquire into the reason for the present revival of stereoscopic work amongst the photographic fraternity," Mr. J. C. Annan made a communication to the Glasgow Photographic Association a few days ago, and which was published in this JOURNAL last week. I see by the report that the discussion which followed was "animated," but it is a pity the "animated discussion" has not been published. But let us consider what Mr. Annan has said.

We are told there are several classes of photographers, and these Mr. Annan divides into three. "The first is the professional, who does stereoscopic work to satisfy an eager public demand to buy them for the entertainment of their friends in the drawing-room." Well, now, from a professional standpoint, is this not one grand testimonial to stereoscopic photography, and the fact that there is an "eager demand?" That they suit the public taste is another point in favour.

The next class of photographer, Mr. Annan says, is the amateur, "who photographs because he desires a relief from the monotony or worry of his daily avocation, &c., and this class hail stereoscopic work as a delightful variety, and *naturally* become enthusiastic over it." (Italics mine.) "They rephotograph many old views, and show their results to admiring friends, who expatiate on the marvellous reality of the appearance."

Now, I ask again, Is this not another point in favour of stereoscopic photography, or are all our "admiring friends" devoid of taste, without soul or artistic feeling, humbugs, or idiots?

The third class of photographer, we are told, photographs for results; they have a soul beyond the dark room. "Their albums are the real end of their work; they like to have pictures of places visited to remind them of a happy holiday, and to be able to illustrate their private and public lectures to less fortunate brethren." Now, in the name of goodness, cannot all this be done from stereoscopic negatives? "A wave, a cloud, the outline of a hill, or a tree branch, is ever a pleasure to them." What nonsense all this attempt at poetry or art is, to be sure. The stereoscope will show the wave, the cloud, or the branch of a tree, far better than most pictures to be found in albums. Before we try to be poetical in photography, we had better be practical. Then, the albums of ninety-nine out of every one hundred amateur photographers are not fit to be seen; they are, as a rule, the receptacle of early efforts and prints that are not good enough to mount in any other way, though sometimes an album may contain reminiscences of holiday rambles; and we can do all this by printing from one end of a stereoscopic negative.

I have before me as I write a stereoscope and a box of fifty stereoscopic slides (glass transparencies) made from negatives taken on a holiday tour. Near the box is an album, containing fifty platinotype prints (quarter-plate size), printed from one end of the same stereoscopic negatives. My friends who visit me have, I believe, the average intelligence of the human race, and dozens of times I have experimented upon their tastes by giving them first the album to look through, and generally in five or six minutes they are satisfied; but the very same persons will often spend as much time looking at one stereoscopic slide, and sometimes longer, if I don't hurry them along, and, when these same friends revisit me, they ask to see my stereoscopic transparencies again; but they never ask to see the album at all. Now, how is this? Let us see what Mr. Annan says again.

In the first place, he submits, "it is impossible to appreciate the artistic qualities of a photograph through any mechanical contrivance, and that to enjoy a work of art the mind must be untrammelled by anything outside of it, for the disturbance created by the necessary fixing of the parts, the adjustment of focus, &c., is a source of irritation which prevents the enjoyment of the beauties of the picture;" and these things are the initial objections of Mr. Annan to the stereoscope.

Now, it is a fact that, in the old days of the stereoscope, thousands of slides were made so very incorrectly, and these, when viewed by stereoscopes, which were equally defective, caused considerable trouble, and undoubtedly did represent natural objects in a very unnatural way, as stage set-scenes or little models.

But all this wrong-doing of the past need not be repeated. There is no necessity for this "fixing" and what is usually understood (erroneously) to be "adjusting the focus." I say again, with emphasis, that with correctly printed slides and properly constructed stereoscopes there is no occasion for any trouble or irritation such as has been mentioned.

But there is a fourth class of photographer not mentioned by Mr. Annan whom I must now introduce. This class of photographer has a propensity for doing things without thinking, and for talking and writing about art, atmospheric renderings, optical, and other matters of which they have but a very limited understanding, and it is such gentlemen whom the student in stereoscopic photography has most to fear in leading them astray.

Mr. Annan asks us "to imagine an artist painting a picture of a view which he looked at through a telescope." Now, this is a remark quite misleading, for it has no bearing whatever on the stereoscope, but might well be applied to taking single pictures with a lens of too long a focus.

Mr. Annan says: "In nature it is impossible to see objects near at hand and objects at a distance in focus at the same time; in the stereoscope, however, the several planes are all seen in focus at once, and thus the effect aimed at by one means is directly annulled by another, with the result that the various planes seem flat portions supported by a little space from each other."

Here we have an instance of the fourth class of photographer whom I have introduced in this short article, and where a little learning is shown to be a dangerous thing. In the first part of the above paragraph Mr. Annan is correct, but in what he says he sees in the stereoscope he is all wrong.

"Focus," or the "several planes seen in focus at once," has nothing whatever to do with the subject. If we look at a natural object five yards away, and then turn our attention to another object fifty yards beyond, we undoubtedly alter the focus of our eyes; but this alteration of focus gives us no idea or appreciation of distance.

It is a fact that "the mind can only concentrate itself on one object at a time," but it is incorrect "that, if an endeavour be made to look at a near object and at a distant object together, it will be possible to do so."

Next, we are treated to some incoherent remarks about atmospheric impressions, and what the painters do, and to which I need not reply further than to say that, if it be possible to obtain atmospheric effects in a single photograph taken by one lens, surely it is equally possible to obtain similar effects in two other pictures made by two other lenses. Then, as I have previously stated, if these two other pictures have been rightly taken and placed in the stereoscope, it matters not whether the subject be atmospheric effects or aereal grandeur, mountain or foreground, *with all on one plane*; this plane, so far as focus is concerned, has nothing whatever to do with the distance-giving power.

It is the varying convergence of the axis of the two eyes that enables us to estimate distance in natural objects, and, when the stereoscopic slides and stereoscopes are made and used correctly, it is possible to appreciate the relief, distance, and perspective due to nature a thousand times better than from any single picture.

W. I. CHADWICK.

OUT-DOOR PHOTOGRAPHY.

II.—CHOICE OF APPARATUS.

THE selection of apparatus is by no means an easy matter for the inexperienced, or, in fact, for any one. There is so much on the market having a plausible look that its very abundance creates the difficulty. If it were only required for "wrapping in lavender," or to put under a glass case, the task would be easy, as perfection of polish and general appearance will suffice, the flimsiness and faddiness of design, with appurtenances for enabling everything to be done except the taking of a decent picture, being, under those circumstances, of little consequence. During the period of the camera craze the descriptive woodcuts of some of these elegant articles called cameras put one more in mind of the vagaries of a circus horse than anything else, being represented as in use while rearing, bucking, front or back downwards, and so forth, and while contorted into a variety of other shapes to show how supple they were, the light conical bellows being as if made of sheet steel, so well it appeared to accommodate itself to each position. Sagging of bellows and loss of parallelism through wear and dropping of parts are, of course, quite unknown in creations of this kind, and mention is not made of the splendid refinements in distortion they will produce if used for interiors with wide-angle lenses unless controlled by a complete battery of levels and plummets. What a nice illustration their use out of

doors in damp weather would make with the bellows tied for support to light girders of firewood with odds and ends of string; and how delightfully another could be made to show the delicate appreciation of the difference in the weight of lenses possessed by their rigid and extending fronts. The requirements of the professional go a little beyond this; he does not need show, and has no time to play with a mere box of tricks. His apparatus must be of a kind to inspire confidence, and relieve the mind from all anxiety respecting its performance; constructed substantially, and of such a design as to do the main things well in hot or cold, wet or fine weather, and capable of standing hard usage without getting out of truth or falling to pieces. There is no necessity for such an instrument to be either clumsy or heavy.

The main features of the most useful pattern of camera for all-round work are square body with reversible back, double extension backward, rising and falling front of good range, lateral front ditto, double swing back, and double dark slides, whose shutters fold round flat. In large cameras the double extension is better when formed of two distinct lengths of bellows joined to a centre frame; the forward one may be conical, the latter always parallel. The support thus afforded at the junction of the two keeps the bellows in better condition, the extra stability being well worth the few ounces extra weight. Cameras under 12 × 10 in size do not need it. Their bellows may be constructed partly conical, the parallel half, where it is joined to the back framing, being small in fold, to ensure perfect clearance with lenses of any description. The weak point of double extension is the sliding base frame. Whether this extends forward or behind, it must be unexceptionably well fitted, and its racking out limited in general use to about two-thirds or so of its length. Its chief defects arise from weakness in being made too slight and bad fitting, either initial or resulting from wear of the sliding tongues and grooves, all of which tend to cause the lens to pitch forward. The evil is likely to pass unnoticed on front extensions; or, if detected, is difficult of correction; whereas, when the lens-board is a fixture to the main base-board of the camera, and the back frame operated by the extending one, any want of truth is made right in the usual routine of setting the swing-back. Bear this in mind, and avoid mere triumphs of the cabinet-maker's art in favour of the more matter-of-fact-looking instruments, to which the right principle of extension from behind has been applied.

The rise and fall of the front, and the play of the lateral one, should be as extensive as possible, consistent with light-tightness. Most patterns of cameras have insufficient rise, not because space is limited, so much as, apparently, a desire on the part of the manufacturer to spare the brass a longer slotted plate would need. He ought to have the privilege of seeing one of his masterpieces with the milled-headed screw out, a penknife stuck in the face of the camera to hold the front higher, as if for the sole purpose of exhibiting to the select company the choice timber and workmanship of the under frame, and how economical his people had been in the blacking up. The defect, although a trifling one, causes much vexation, for it has to be dealt with just at the time when any disturbing influence is better absent.

With respect to the swings of the back, both should move on pivots at their respective centres in the old-fashioned way, the distance and position of the focussing screen in respect of the axis of the lens thereby remaining constant, and, being uncomplicated by other disturbing elements, which swing fronts, hinged sides and bottoms, and so forth, introduce, their benefits are realised with less expenditure of time and trouble. See that there are no loose fixings, and that all may be securely bound in any position within their range into one rigid piece.

If the instrument be ordered or purchased direct from a manufacturer, instruct him to have all grooves and tongues, both of camera and slides, well embodied with polish and papered off. These are just the places most in need of varnish to prevent swelling and sticking of shutters and sliding frames; but, as the labour and polish has no decorative result when applied to them, they are usually left untouched, to become an intolerable nuisance after being a few hours out in damp weather. Before putting it into general use, ascertain whether it is light-proof, and see that its dark slides are all likewise safe and in accurate register with the ground surface of the focussing screen. Failing to register was a common fault. In the course of my experience I have known first-class lenses to be condemned as worthless, and have on many occasions pointed the evil out to brother photographers, who were at their wits' end to know what was amiss, and, on one very important occasion, affording a chance which has never been repeated, I was badly sold myself. A new camera had been purchased for the event, and one slide only tested. This happened to be right, just enough to make a fool's paradise, with the usual result. The introduction of machinery, and the more free use of templets in the manufacture of the modern camera, together with the shelving of lenses of the "baby" lens type, has mitigated, but not quite cured, the evil.

Among the minor points give the preference to rack work, as the wear of the grooves is less, and the motion truer than with a winch screw; have no loose screws or parts, and see that the interior of the camera is well covered with a coating of deep matt black.

A large focussing cloth, specially made for use with the camera, should be provided, with one of its small sides sewn with a hem to three sides of a moderate size square of the same material, in which a large circular hole has been cut at the centre, and also hemmed. Into both hems a piece of elastic webbing of suitable length is run and fastened. This forms a kind of hood or bag to completely envelop the front of the camera, the remainder of the cloth passing backwards to cover the tail-board in the usual way. A thing of this kind never gets blown away, it effectually shelters the camera, and offers no obstacle to the rapid manipulation of the camera fronts, whose screws are released or tightened through the central aperture surrounding the lens. I prefer a double thickness of fine "silesia" sewn together round the edges, and a few times across to keep it neat and shapely. A second one of the usual form is needed for use with the dark slides.

Of tripods two are necessary, one being of the ordinary pattern, in which each leg consists of two pieces of stuff, jointed near the foot, or in one piece ripped two-thirds of the way down. This type is very steady, and is easily set up. Avoid all "gimcracks" with a dozen joints and spider-like limbs; leave these to the professors of the "fuzzytype" school, who probably may find the art qualities of their productions much enhanced by the employment of these unsteady articles. The second should be of a sliding pattern about five feet or so high, the extension of the legs giving another four feet six or so, and have a ball-and-socket head of good design. I have seen and used several, both ancient and modern, nearly all the latter failing in one respect, in that the binding of the screw, through being direct on the ball, soon wears this so much that accurate adjustment is almost an impossibility. The first pair of tripods I ever set up when I entered the ranks, seven or eight-and-twenty years ago, were two of the old French ball-and-socket pattern. The design of these was about right. Instead of the ball being bound as above, it was slightly scored, and rested in a semi-globular cavity on the upper side of the wooden head of the tripod, a second hollow piece having a central hole for the stalk of the ball to pass through, confined it from above, and was drawn with force upon it by means of three bolts, which, after passing through the head of the tripod, were secured in a brass frame, whose centre was tapped for a thumb-screw to bear on the under-side of the tripod head. By these means the ball was pinched with great force in any position without slip or disturbance of any kind.

JOHN HARMER.

Our Editorial Table.

MR. GEO. PENDRY, of Nottingham, has submitted to us some specimens of photo-ceramic work on china, which, both as examples of the capabilities of the process and as photographs, we are pleased to pronounce excellent. They are highly glazed, which, if anything, enhances the beauty of the pictures. Mr. Pendry, we believe, makes a speciality of ceramic work for the trade. Certainly the examples before us in softness and finish rival any we have seen.

VERNON HEATH'S RECOLLECTIONS.

London: Cassell & Co., Limited.

THE "recollections" of a veteran photographer, like Vernon Heath, will necessarily be perused with interest by photographers of all classes, for his fine appreciation of art in connexion with photography, and the surpassing excellence of many of his pictures have, doubtless, conduced to hasten the time when something else than mere technical skill is held to be requisite. The first part of the work relates largely to Robert Vernon, who, in 1847, presented his collection of pictures to the National Gallery; the remaining part is relegated to the author's connexion with photography which, at the death of his uncle, he adopted as a profession. He, in this capacity, took the last photograph that was obtained of H.R.H. the Prince Consort, and *apropos* of which he read a paper, on the reproduction of negatives, at a meeting of the Photographic Society of London, in 1862, which he claims was the first public announcement of enlarging from negatives by the use of a transparency. There is, perhaps necessarily, much of the

personal element running through Mr. Heath's work, which, as we have said, will prove of interest to photographers, especially to those who wish to know what took place in former times.

Fallowfield's New Celloidin Silver Emulsion Paper.

A sample of this paper received from Mr. Jonathan Fallowfield having been carefully tried we find that it is highly sensitive and yields good tones. When taken from the printing frame, following the directions given, it was transferred directly to the toning and fixing bath, the composition of which is as follows:—

Distilled water	20 ounces.
Hyposulphite soda	4 „
Ammon. sulphocyanide	½ „
Acetate of lead	1 drachm.
Nitrate of lead	1 „
Powdered alum	1 „
Citric acid	1 „
Chloride of gold solution (1 grain in 1 drachm)	4 drachms.

In this it acquired a dark purple tone, and also became fixed. This paper will, we doubt not, take its place among the favourite brands now on the market.

Photo-engraving.

By Carl Schraubstadter, Jun., St. Louis, U.S.A.

This is undoubtedly a most useful and practical work by one who appears to have an intimate acquaintance with photo-engraving in all its branches. The author treats the subject in the most thorough manner from the fitting up of the atelier, the method of preparing and intensifying negatives suitable for the work, the selection, polishing sensitising, printing, and etching of the plates, up to the mounting on the blocks so as to be ready for printing. The work is comprehensive, and is not confined to one system alone but embraces all that are now practised from line to half-tone subjects.

PATENTS COMPLETED.

Improvements in and Relating to Masks and Binders, and Apparatus for Mounting Same on the Glasses of Magic Lantern Slides, Photographs, Stereoscopic Slides, and the Like.

No. 3823. David Alexander Abercrombie, 34, St. Andrew-square, and Alexander Robertson Fletcher, 21, Queen's-crescent, both in the City and County of Edinburgh.—*February* 20, 1892.

This invention has reference to and comprises a combined mask and binder, and means of, or apparatus for, mounting or attaching same to the glasses of magic lantern slides, photographs, stereoscopic slides, and the like, for protecting and binding them airtight; and which will be more simple and efficient than what has been heretofore in use.

The improvements consist first in making a mask and binder combined in one of gummed paper or cloth, or equivalent material. This is effected by cutting the paper or cloth of a suitable size to bind round the edges and over the back of the glasses, plain on the outer surface, and gummed or cemented on the inner surface, with a large circular or other opening in the centre. The binding edges would be cut away at an angle of forty-five degrees or so at the corners at that part of the mask which is to fold over and meet each other on the back of the glasses, leaving a square tongue part at the centre of each corner, equal to the thickness of the glasses, attached by one of its sides to the two opposite folding edges of the mask, so as to overlap and cover the corners of the glass which it binds, before the other two opposite edges of the mask are folded over. These combined masks and binders, cut and formed in the improved manner described, may be thus folded over and attached to the glass by hand, but would preferably be mounted by our new or improved slide mounter or apparatus. This consists under one arrangement of a square or rectangular open frame, preferably of wood, of the size of the glasses internally, with four lateral sliding sides or bars at its upper part, having an elastic band, or other binding springs surrounding them, and with a removable bottom or solid part working within the back part of frame to support the glasses. This solid back part would preferably consist of two square or rectangular pieces connected to each other at some distance apart by pins and sockets with springs, or with a helical, or other spring, between the two parts, so that the inner part will have a collapsing or yielding elastic action when the glass plate is pressed towards it as hereinafter described, while the outer bottom part would be held in a checked recess in the lower part of the frame by swivelling catches or otherwise. In using this apparatus the combined paper or cloth mask and binder so cut is moistened on its gummed upper side, and placed with its dry side within the upper part of frame made to the size of mask, over the edges of the four lateral sliding parts, which are dovetailed and meet each other at their inner corners, and on the upper surface of the spring bottom, which is brought up by the springs within and to the upper part of sliding sides, and the glasses are laid over the mask and spring bottom, or the mask may be gummed to the front glass before being inserted in frame. The glasses are then pressed inwards by hand, by which action the mask binder is carried along with them through between the spring-pressing sides, and bound round the edges of glass and depressed with inner part of spring bottom at back part of frame. The two opposite folding or sliding spring sides of frame, which fold up the edges of the mask, and to which the corner tongues of mask are attached, are highest, and come first into action to fold up these two edges, and fold in the four end tongues before the other two opposite sliding sides come into action, these being less in depth, and so fold up their edges over the tongues, which seal the ends airtight at the same time as sealing the four edges. The glasses and spring bottom are then pressed further down, until they pass the lower edge of the spring sliding sides, which now slide inwards over the upper glass and press down the edges of the mask to adhere on to the upper surface edges of the glasses, assisted by the action of the springs, these edges meeting each other in a mitre joint at the corners. In some cases the lower surface edges of these sliding bars might be fitted with vulcanised indiarubber or other soft material, to so fold and press the edges of the mask on to the glass. Each glass slide can then be removed by taking out the spring bottom of the frame, which is again inserted before mounting the next glass with a mask and binder.

To assist in placing or inserting the glass or glasses centrally over the moistened gummed mask in these frames, a loose portable frame, holding these, may be employed, fitting the mounting frame on pins or otherwise, and with turn latches or slides moved in unison, which would allow the glass to drop out of this upper movable frame down on to the centre of the mask in the fixed frame. Or, otherwise, corner guides may be mounted on hinges on the fixed frame, to be folded over after putting in the moistened mask, and so guide the glasses down on to the mask, and be folded out of the way again as soon as the glasses were placed in position.

This apparatus may also be used for folding and attaching the ordinary ornamental sheet metal outer securing or binding mounts over the glasses and masks.

Improvements in Photographic Apparatus.

No. 3942. John Naylor, The Laurels, Nightingale-road, Harlesden, Middlesex.—*February* 20, 1892.

The object of my invention is to improve the well-known roller slides in use in photographic apparatus, and particularly those known as the Eastman roller slide. In these slides, as now in use, the perforations for the purpose of indicating the point or points at which the film should be divided after each exposure are indefinite, that is to say, they do not actually indicate the exact line on which the film should be divided by crossing the same vertically, and there is danger of mistaking the points, by reason of there being four or more perforations at the top and bottom edges of each section of the film (*i.e.*, each exposure); moreover, there is no means of registering the number of exposures, or of indicating if the last exposure has been wound off.

Now, by my invention I perforate the film on each exposure vertically, or across the same in the line of division, and at the necessary point only. I further automatically register, by the winding of the film on the roller, the number of exposures made, and further indicate if the last film exposed has been wound off or not.

In carrying out my invention, I take an ordinary Eastman roller slide frame, and cut a slot in the measuring roller extending a little beyond the centre and the whole length of the roller, and at each end of the roller I attach a hollow metal cap, one of which terminates in a short hollow shoulder, forming a bearing engaging with the pin on which the roller usually revolves. To the other cap is fixed a small wheel, which gears with a second wheel, as in the Eastman apparatus. In the slot formed in the roller I fix a thin metal bar or strip, carrying points or teeth, which is caused to rise from the slot in the roller and perforate the film on each withdrawal or replacement of the shutter. The bar or strip is enclosed between two other thin strips of metal, forming a case and carrying inclined planes, up which the centre piece, carrying the points or pins, rides on being actuated.

The slide shutter carries, on the outer side, a catch engaging with a spring slide, which, pushed by the hand or finger, releases the shutter, and at the same time actuates a spindle attached to the strip or bar carrying the points which make the perforations.

To register the number of exposures, I fix on to the frame of the slide, and conveniently near to the end of the roller, a toothed wheel, indicating units, carrying a pin gearing into a smaller toothed wheel, indicating tens. On the spindle of the wheel already described as the second wheel I attach outside the frame a collar, having a projection, which engages with the teeth of the unit

registering wheel, so that after each exposure the unit registering wheel is turned one point. The collar has an indent, in which engages the tooth attached to a lever spring, which prevents overwinding, and produces an audible "click" when the exposed section of film has been wound off. This point or tooth on the lever spring is released from the indent in the collar by actuating the before-mentioned releasing catch on the shutter, and shows at a glance whether the film has been exposed and is ready for winding up or not.

The bearings of the two registering wheels are so arranged that they may be put in and out of gear with each other for the purpose of re-setting.

Improvements in Dark Slides for Photographic Purposes.

(A Communication by Paul Tournachon, of 58*bis*, Chaussée d'Antin, Paris, France.)

No. 6572. James Yate Johnson, 47, Lincolns-Inn-Fields, Middlesex.—*February* 20, 1892.

My invention relating to dark slides for photographic purposes consists in improvements in the construction and arrangement of the parts connected with the film carriers, and is partly applicable to other dark slides, as hereinafter explained.

The dark slides, according to my invention, enable a large number of exposures to be made upon the paper or film, which is of considerable length, and an indicator is employed to show the number of exposures.

The supports of the rollers slide into a light-tight case, closed in front by a shutter, which is removed during exposure, and inserted for the time into a groove or slot at the back.

When the shutter is removed, the opening through which it is withdrawn is instantly closed by a transverse slide, actuated by a spring and provided with an incline or bevel enabling it to be pressed back when the shutter is returned to its place.

This transverse slide also exerts upon the shutter sufficient pressure to ensure the effectual exclusion of light. These arrangements are applicable to dark slides of any construction.

The spool is composed of four segments, so put together as to present two longitudinal openings arranged at right angles, and turns on two fixed pivots. A disc at one end of the spool carries pins, which engage in holes in the end of the spool. The end of the film is inserted into one of the longitudinal openings, and is secured by a plate sliding in the other opening arranged at right angles with the first, so as to bend back the end of the film and retain it firmly in position.

The receiving roller is similarly constructed, and is capable of being rotated from the exterior by means of a hinged key or folding handle.

The movement of the film or paper is controlled by a pivoted brake spring with two arms, whose extremities engage with the toothed edges of discs connected with the spool and the receiving roller. A lever pressing the brake arm against a fixed stop compels the brake to exercise a constant or uniform pressure upon the roller discs. Owing to the shape of their teeth, these discs, and consequently the rollers with which they correspond, can only turn in one direction. The brake can be released by removing the pressure of the lever.

The said lever is retained in position by a spring catch, which, when released, enables the roller and spool to turn freely in either direction.

The perforating or registering roller is fluted, to prevent slipping of the paper or film, and is of such diameter that, when it has made exactly two revolutions, for example, sufficient of the film is unrolled for one exposure. Inside the registering roller is a roller of smaller diameter, rotating in bearings in the ends of the registering roller. The small roller is arranged eccentrically to the registering roller and a wheel on the axis of the eccentric roller gears with a pinion, having, for example, half as many teeth as the wheel on the axis of the registering roller.

A series of small blades or prickers, carried by the eccentric roller, project through openings in the side of the registering roller when the eccentric roller is in a certain position, and the relative diameters of the gearing is so calculated as to cause the said prickers to project once for every two revolutions, for example, of the registering roller, and cause the successive negatives to be separated from one another by a series of holes.

The film drawn from the spool passes over the perforating or registering roller, and is drawn in front of the slide where it is exposed. It then passes round a plain guide-roller, and is wound upon the receiving roller.

The number of exposures is indicated by the number of revolutions made by the registering roller. This number is recorded by two discs, one disc indicating units, and one indicating tens, for example. These discs are concentrically arranged, the disc for the tens accomplishing the tenth part of a revolution, while the unit disc makes a whole revolution. The figures are preferably formed on the flat sides of the discs in order to economise space and enable the counter to be contained in the thickness of the side of the case. A stud or pin on the end of the registering roller drives a star wheel intermittently, causing it to advance one a tooth at each revolution of the roller, and this movement is transmitted to the indicating or registering mechanism by suitable gearing.

The tens disc rotating concentrically with the unit disc is provided with ten equidistant holes, which successively coincide with a hole in the unit disc situated on the radius corresponding to zero. A spring pin enters this hole so as to lock the disc together.

A metal plate, covering the indicator mechanism, is provided with an orifice showing the figures, and also enabling the inclined extremity of spring of the locking pin to move forwards each time that the zero is presented at the orifice. This movement locks the unit disc and tens disc together once at every revolution of the unit disc, and displaces the tens disc to the extent of one figure, after which the inclined end of the locking spring comes in contact with the edge of the orifice in the covering plate, and releases the said tens disc, which then remains stationary until the unit disc has completed another revolution.

Each time the indicator advances a unit, the end of a spring falls from one tooth to another of a ratchet wheel, causing a clicking sound, indicating that the roller has been sufficiently rotated. This device also renders it impossible to turn the roller and counter the wrong way.

The ratchet wheel may be arranged to actuate a bell or other sounding device.

A tension roller is carried by two springs, which cause it to press regularly on the paper or film.

The plates carrying the journals of the rollers are connected and stayed by suitable rods, and the plates at the sides are cut away and recessed to facilitate the working and the insertion of the film.

Hinged flaps are provided at the sides of the slide to prevent the film getting torn at the edges when sliding the plates carrying the rollers into the outer case of the slide.

To obviate the waste of paper or film, in roller slides arranged as herein described or otherwise, and which is involved by the ordinary methods of attaching the ends of the films to the rollers, I attach to the end of the film a linen band of the same width as the film, and to this linen band is attached a spring clip, one of the jaws of which is provided with a slot or opening. The film is drawn between the jaws and the end inserted into this slot, and secured by sliding a rectangular binder or wire over the projecting end of the film. This linen band is then attached to the roller, and replaces that portion of the film, which would otherwise be wasted.

The dark roller slides, according to my invention, may be attached to the camera by the usual sliding motion or in any other suitable manner.

Improvements in Photographic Printing Processes.

No. 7312. William Walker James Nicol, Mason College, Birmingham.—*February* 27, 1892.

My invention has for its object the production of photographic pictures or images in silver by improved methods of carrying into effect the processes described in the specification of my former Letters Patent, No. 5374, dated March 29, 1889.

Whereas the processes therein described and set forth, though yielding excellent results so far as the quality and tone of the resulting pictures were concerned, were apt, inasmuch as the solutions employed for development contained soluble salts of silver, to stain the hands of the operator, it was found that this formed a serious objection to their general employment.

I therefore now proceed acording to the following method—that is to say, I coat, in any convenient way, paper or other material with an aqueous or other solution of a ferric salt. This may be one or other of the following: ferric oxalate, citrate, tartrate, or other ferric salt which is sensitive to light. These may be employed singly, or mixed together in suitable proportions, with or without the addition of citric, tartaric, oxalic acids, or their sodium, potassium, or ammonium salts. To the above solution is also added a suitable quantity of a silver salt, and the whole is thoroughly mixed together. The above solutions may be applied to the paper or other material, if so desired, separately, and in any order, and in such relative quantities as may be found to give results most suitable for the purpose in view.

After the material, thus prepared and rendered sensitive to light, has been dried, it is exposed to light under a negative or other screen. I then proceed to develop the ferrous image produced by the action of light with a solution containing a salt of citric, tartaric, oxalic, boric, carbonic, or acetic acid, with sodium potassium or ammonium; or mixtures of these with one another in such proportions as may be found to give the requisite tone and brilliancy to the resulting images. When certain of these mixtures are employed, the addition of a small quantity of potassium chromate, or other suitable oxidising agent, is necessary to ensure contrast and purity of the high lights of the picture.

The resulting prints are then washed in several changes of dilute ammonia, to which may have been added a citrate or tartrate of potassium sodium or ammonium.

Or, I adopt the following method. The paper or other material, having been prepared as above described, is exposed to light as before, and is developed at once on the dilute ammonia mentioned above, with or without the addition of one or other of the salts mentioned as entering into the composition of the developer as described above.

Or, I adopt the following method, viz.:—I prepare the paper or other material with one of the above ferric salts, and a suitable amount of one of the above-mentioned developing salts, and a solution of a silver salt. I thus obtain a sensitive surface which attains its full depth of tone by the action of light alone. The print then requires only to be washed in the dilute ammonia above mentioned.

I. In practising my invention, according to the first method above described, I use by preference solutions of the following composition:—

Water, one hundred (100) cubic centimetres.
Ferric oxalate, fifteen (15) grammes.
Silver nitrate, three (3) grammes.

The above forms the sensitising solution.

The developer is as follows:—

Water, one hundred (100) cubic centimetres.
Rochelle salt, ten (10) grammes.
Borax, seven (7) grammes.

To this is added one-tenth (0·1) to four-tenths (0·4) of a cubic centimetre of a five (5) per cent. solution of potassium chromate.

The prints are immersed in the above solution for fifteen to thirty minutes, and are then washed in two changes of the following:—

Water, one (1) litre.
Ammonia (specific gravity = 0·880), three (3) cubic centimetres.

The prints are then washed in water and dried.

II. According to the second method above described, I use the following solutions:—

Sensitising Solution.

Water one hundred (100) cubic centimetres.
Ferric citrate ten (10) grammes.
Oxalic acid three (3) grammes.
Silver nitrate three (3) grammes.

After exposure to light the prints are immersed in

Water one (1) litre.
Ammonia (spec. grav. = 0·880) six (6) cubic centimetres.
Sodium citrate twenty (20) grammes.

They are then washed in the dilute ammonia described in the first method.

III. According to the third method above described, I use the following solutions :—

SENSITISING SOLUTION.

Water, one hundred (100) cubic centimetres.
Ferric oxalate, fifteen (15) grammes.
Potassium oxalate, three (3) grammes.
Silver nitrate, three (3) grammes.

After exposure to light, the prints which should have attained their full depth are washed in the following :—

Water, one hundred (100) cubic centimetres.
Sodium citrate, three (3) grammes.
Citric acid five-tenths (0·5) of a gramme.

They are then washed in the dilute ammonia and in water, and dried.

Having now particularly described and ascertained the nature of my said invention, and in what manner the same is to be performed, I wish it to be understood that I do not limit myself to the proportions above stated, but alter them in various ways with the tone or colour required in the finished picture, and I claim :—1. The use of paper or other surfaces prepared with mixtures of ferric and silver salts as described above, to be used for the production of photographic images in silver along with the class of developing solutions already given and particularly referred to in my second claim. 2. The use of developers as described in the above first and second methods in conjunction with paper prepared with ferric salts as above described. 3. The use of the sensitising, developing, and washing solutions particularly stated above, and there set forth.

IMPROVEMENTS IN PHOTOGRAPHIC CAMERAS AND APPARATUS CONNECTED THEREWITH.

No. 3603. ALEXANDER MILLER, Hollyhurst, Clapham Common, London.—*February* 27, 1892.

MY invention is of two parts.

I. The application of a swing back to hand and other cameras in combination with, and attached to, a horizontal swing focussing screen on the top of the camera.

II. The use of a mirror, fixed to or near the lens, and capable of being placed at an angle in front of it, so that objects at either side of the camera or above it can be photographed without its being pointed directly towards them.

1. To carry out the first part of my invention, I make—

(A) The back of the camera with a vertical swing movement, and connect it by a system of levers, or otherwise, with a horizontal swing focussing screen on the top of the camera, in such a way that the back and the screen always preserve their relative positions at right angles to each other when the back is tilted.

Or (B) I effect the same object by making inside the back of the camera a case to contain plates or roll-holder, this case being made to swing vertically and being connected with the horizontal screen in the same way as described above.

I apply either of the foregoing arrangements preferably to the type of hand camera in which the image from the principal lens is, for focussing purposes, reflected from a mirror inside the camera to a screen at the top; but I propose to apply it also to those which have a small separate focussing screen and "finder" lens. In either case I am able to tilt the camera, to see on the screen the amount of distortion thereby caused, and to correct it by the swing back, as in an ordinary camera.

2. To carry out the second part of my invention, I fix a mirror to, or near, the lens of any camera, so hinged or pivoted that it can be placed at an angle in front of the lens, and thereby objects at the side of, or above, the camera are reflected into it without pointing it directly towards them. In hand cameras, I place the mirror preferably in a front chamber enclosing the lens, with an opening at each side of this chamber to allow light from objects at the side to fall upon the mirror, which can be placed on either side of the lens.

Having described my invention, I now state what I claim as novel, viz., 1. The use in hand cameras of a vertical swing back or case, in combination with, and attached to, a horizontal swing focussing screen, substantially as described above. 2. The use, in connexion with all cameras, of a mirror placed at an angle in front of the lens for the purpose of photographing objects at the side of, or above, the camera.

AN IMPROVED PHOTOGRAPHIC CAMERA.

No. 1730. AUGUSTE ALEXANDRE DEHORA, 8, Rue des Hautefeuilles, Paris, France.—*March* 5, 1892.

THIS invention relates to an improved spring folding photographic camera, capable of being collapsed within such small dimensions as to admit of its being carried in the pocket. It may be provided with any suitable lens and shutter and is used at a fixed focus.

The camera is constructed in the manner of a "Gibus" hat, the front and back being connected together by means of toggle-jointed links, to which springs are attached so as to retain the toggle joints either in the folded position or in the expanded position. A black cloth covering encloses the springs, and forms the collapsible part of the camera body which is distended by the toggle joints, there being a cloth covering within and without the said joints.

It is preferred to use spiral springs, although other forms of spring may be used, and the form of the camera may be varied from that shown.

Meetings of Societies.

MEETINGS OF SOCIETIES FOR NEXT WEEK.

Date of Meeting.	Name of Society.	Place of Meeting.
April 4	Dundee Amateur	Asso. Studio, Nethergate, Dundee.
,, 4	Halifax Camera Club	
,, 4	Peterborough	Museum, Minster Precincts.
,, 4	South London (Annual)	Hanover Hall, Hanover-park, S.E.
,, 4	Stereoscopic Club	Brooklands Hotel, Brooklands.

,, 8	West London	Chiswick School of Art, Chiswick.

LONDON AND PROVINCIAL PHOTOGRAPHIC ASSOCIATION.

MARCH 24.—Mr. L. Warnerke in the chair.

Messrs. W. Cobb, H. Rapson, and E. A. Golledge were elected members of the Association.

The following question from the box was read,—"What would be the length of focus and value of the stops if the back combination only of an eleven-inch rapid rectilinear or eight and a half inch wide-angle lens were used? What would be the disadvantages, and would there be any pronounced distortion?"

Mr. W. E. DEBENHAM replied that, if the lenses were symmetrical, the length of focus would be about double. The value of the stops would be divided by four, that is, each stop would require four times the usual exposure given. There would be curvature of the lines if architectural subjects were taken to the full field.

Another question ran: "What is the difference between chemical and physical restrainers?" which elicited no reply, as the questioner's meaning was not clear.

A third question asked: "What alteration took place in the composition of the ferrous oxalate developer after development of the plate?" and to this it was replied that a portion of the developer was converted into ferric oxalate.

Mr. W. H. HARRISON read a paper on *Foreign Photographic Institutions and their Influence* [see p. 213]. At its conclusion,

Mr. F. A. BRIDGE referred to the excellent collotype work of M. Maes, of Brussels. On a recent visit there he (Mr. Bridge) had seen reproductions of various makes of lace and of old gateways and citadels in Belgium, made by M. Maes, which were very fine indeed. M. Maes would gladly give members of the Association any information.

Mr. A. TATE said that at Lausanne he had been much impressed with the facilities which existed there for obtaining information on the principal photographic subjects. He also said that in Norway and Sweden, in the ordinary course of compulsory education, every student had the opportunity of learning at least three living languages, which there was no doubt in the battle of life would be of the greatest possible advantage to him.

Mr. DEBENHAM said that he would like to see education carried out as much as possible, but in the battle of life they often found English people without much education had the faculty—the business faculty—of getting on. He admired education on scientific matters, and wished to forward it, but thought it rather independent of success in the battle of life.

The CHAIRMAN said that in the last number of Nadar's *Paris Photographie* he was surprised to find an account of a photographic educational establishment, in which the great necessity of photo-technical education was insisted on. Quite recently in France photo-mechanical printers were in great request, but could not be got, and the work had to be given to Germans. In this respect England was unfortunate, and it indicated clearly the need of photographic technical education, which the French Government were just providing.

Mr. P. EVERETT said he should no doubt be called a heretic; but he, for one, did not deplore the fact that we had to send to Germany when we wanted a good collotype-process man. This raised the whole question of foreign trade, which was lost sight of in this matter of technical education. Was it desirable to set up photo-mechanical printing on the footing on which it existed? Was it a desirable industry, and did the workmen abroad get better wages than the average printer in this country? They were less paid than they would be here. Those who deplored that this country could not undertake such work forgot that by far the best thing was for it to produce those articles which were within its own environment, and so leave production to the ordinary course of trade.

The CHAIRMAN referred to the disastrous effects upon photo-mechanical.

houses in this country of foreign workmen engaging with them, and then being tempted elsewhere by offers of higher wages. Photo-mechanical illustrations for books were just now very popular, but they very often had to go abroad for them. England was a large publishing country, but it went in a great deal for the cheap and nasty. Look at the paper on which many of its publications were printed! In London they could not get paper suitable for printing photo-mechanical work; there was some secret in imparting a smooth surface to it. At the Conference of the Camera Club on the previous day Mr. Pennell had referred to the bad paper employed as not printing illustrations well.

Mr. T. Bolas said that Mr. Everett's contentions were not in any sense arguments against technical education. The spread of technical education enabled each nation to take advantage of its environments.

Mr. Harrison having replied to some questions put to him, the Chairman's slides, illustrating his recently delivered paper on *Photo-technical Education on the Continent*, were exhibited, at the conclusion of which, and in the course of further remarks, he took exception to Captain Abney's recent plea for a modest Photographic Institute, with modest professors, &c., asking whether it was worth while to start on a small scale! An English establishment should not be inferior to those he had described that night. As an example of what foreign countries could do in the matter of exhibitions, the Moscow Photographic exhibition, just opened, had twenty rooms devoted to exhibits, two being set apart for a scientific section. There was also to be seen there the first attempt made to photograph the retina of a murdered woman. The exhibitions in Vienna and Belgium were also very fine, and here, in London, the Photographic Society of Great Britain held its exhibition in one room only.

Votes of thanks to Mr. Harrison and Mr. Warnerke terminated the proceedings.

North Middlesex Photographic Society.—March 28, Mr. F. Gaudon in the chair. Mr. C. Beadle delivered a lecture on *Enlarging by Artificial Light with the Use of a Lantern*. Having dealt with all the factors to be considered, the lecturer explained his apparatus, and made a 15½×12 print from a half-plate by means of it. The apparatus consisted of a lightly made box, three feet long, having a light-tight door at each end and a light-tight lid. A movable platform fitted inside the box, and rested on the bottom. Upon one end of this a camera, bearing a six-inch lens, was attached by the tripod screw. At the other end was a frame glazed with clear glass, having behind and in contact a sheet of ground glass. This frame moved backwards and forwards on runners. The negative was fitted in a rabbet in the doorway at the end of the box to which the camera was fitted. The lens and focussing screen were placed roughly in position, according to the distances given in enlarging tables. Exact focus was obtained by looking through the door behind the focussing screen, and moving the lens and screen to their proper position. These points were marked upon the platform for future use. A sheet of Eastman's "rapid" bromide paper was then, by non-actinic light, placed in the frame face to the clear glass, and kept flat by the ground glass placed at the back of it. The frame or slide being slipped back into position, the box was closed with the exception of the door in front of the negative. Exposure was made by magnesium ribbon, burned at one inch from the negative, care being taken to secure even illumination by moving the ribbon from point to point. As the negative was rather dense, and stop 16-*f* used, six feet of ribbon were required. Mr. Beadle used ferrous oxalate, strongly restrained, and applied a normal developer by means of a tuft of cotton wool to bring up lagging detail where necessary. The print proved an excellent one. Contact prints were then made on Eastman "rapid" and "permanent" paper for the benefit of the younger members who had not previously worked the process. Mr. Beadle stated that he commonly used the apparatus for daylight enlarging. He fitted the bromide paper or sensitive plate in the dark room, carried the box into the garden, and, standing it on end, made the exposure by opening the door and exposing the negative to the sky. A lecture on the *Detection of Crime by Photography*, by Dr. Jeserich, was, by the kindness of the Photographic Society of Great Britain, brought before the Society as one of the affiliated societies. The lecture was thoroughly wrought out, and of absorbing interest. Next meeting will be held on April 11, when Mr. J. Gale will give an address, illustrated by lantern slides. Visitors will be welcome.

Kensington and Bayswater Photographic Society.—March 28, Mr. Leslie Selby presiding.—An exhibition of lantern slides, principally from photographs by members and their friends, took place. The collection consisted of river and wood scenery, copies from woodcuts and engravings, portraits and interiors, and several photographs of microscopic slides, among which were a very fine group of diatoms, parts of insects, &c. The exhibition of the different tones capable of being produced by varying the exposure and development gained considerable attention. Next meeting, April 11, when Mr. J. D. England will give a paper on *Celluloid Films*.

West London Photographic Society.—March 25, the President in the chair.—Mr. Whiting read a paper bearing on the art side of photography, rules of composition, principles of selection, &c., illustrated by a number of lantern slides, which showed that Mr. Whiting, unlike some photographers, carries into practice the theory he preaches, and evidently with success. He exhibited an ingenious view meter of his own construction, capable of being used with different lenses. The annual dinner will take place on May 13.

Putney Photographic Society.—March 26, Rev. L. Macdona in the chair.—A practical paper on *Printing Processes*, the sixth of the series, was read by Mr. J. A. Hodges, who described the principal features of the various printing methods—silver, bromide, platinum, &c. The preparation of home-sensitised paper was fully dealt with. After some discussion, a number of fine slides, illustrating a tour in North Devon, were shown, the lecturer's graphic and amusing description being highly appreciated. Next meeting, April 13, *Mounting*, by Mr. A. Horsley Hinton.

Richmond Camera Club.—March 25, Mr. Davis presided.—The Secretary read the translation of Dr. Jeserich's paper on *Photography Applied to the Detection of Crime*, lent by the Photographic Society of Great Britain, which, with its accompanying lantern illustrations, proved of the greatest possible interest, as showing how photography—and especially photo-micrography—has been made by the learned Doctor to supply irrefutable evidence where no other means would avail of the identity of criminals, the falsification of documents, and other indispensable links in the chain to drag the malefactor to justice; how, too, it has been the direct means of clearing wrongly suspected parties, and what a vast field of usefulness in the direction indicated the science is destined to fill.

South London Photographic Society.—March 21, exhibition of lantern slides by members, which were freely criticised. The criticism will no doubt prove very beneficial to the members in their work during the present season. The chief exhibitors were Messrs. Bailey, Dishman, Ester, Fellows, Farmer, and Oakden.

Blackheath Camera Club.—March 8, Mr. W. Farrington (Curator) in the chair.—Mr. E. J. Wall lectured on *Colour Photography*, and exhibited prints in illustration of various processes from the first discoveries of Collen to the latest development of the present time. In the course of his remarks the lecturer said, Collen, in 1865, first contended for making plates sensitive to the primary colours, from which subsequent good results have been obtained. To give some idea of the process, take three colour-sensitive plates, and expose them on the same object behind red, yellow, and blue-coloured screens, each of which cuts out respectively the other rays of colour not required to act. Collotype plates are then made, and inked up in corresponding colours, the superimposed printing effect of which gave a very good result. Respecting the chemicals used for preparing colour screens, soluble Prussian blue will cut out the red and yellow rays, and allow the blue to act. Helianthin cuts out the red and blue for the yellow and green to act, and bichromate of potash cuts out the blue and yellow to let the red act. Vogel, who discovered the optical sensitisers, goes still further, and proposes to make seven negatives sensitive to the colours of the spectrum, to be printed in the same way. Ives's *modus operandi* to show natural colours is by use of the lantern, fitted with three lenses, and screens so arranged as to superimpose the pictures when displayed on the sheet, while Scott works in a similar way with four lenses. Albert, of Munich, has made some advances in this branch, but his process of working is a comparative secret. At the close of the paper some new lenses and work done by the same were shown, and a novelty in celluloid lantern slides and a carrier, concluding with a few new formulæ for developing gelatino-chloride prints.

West Kent Amateur Photographic Society.—March 25, Mr. A. R. Dresser in the chair.—Mr. Reffell gave a demonstration with an electric light (arc lamp) applied to the lantern slides by Messrs. Foy, Grant, Dresser, Reffell, Taylor, and Court were shown. Several photographs were taken by the same light, and good results obtained.

Birmingham Photographic Society.—March 23, last lantern evening of session.—A very fine selection of slides was passed through the lantern by Mr. E. Howard Jaques before a numerous audience. The first slides shown were a series loaned from the Camera Club, London, and comprised some splendid animal studies by Mr. Gambier Bolton, and various slides by Major Knot and Messrs. Stroh, Conway, Maskell, Green, &c., and Mr. Dresser's celebrated climbing dog studies. Mr. W. J. Harrison, F.G.S., who presided, announced that nearly 500 photographs had been sent in for the Society's annual competition and exhibition, which is to be held on April 5, 6, and 7.

Oxford Photographic Society.—March 24.—Mr. P. Lange lectured on Norway, in aid of the Radcliffe Infirmary. Mr. Lange soon made the audience feel that the encomiums placed to his credit in advance were thoroughly deserved. The wildest mountain and river scenery and some charming, quaint views of Norwegian towns and villages were placed in rapid succession upon the enormous screen. The choicest bits of all were some gorgeous cloud effects, sunrise, sunset, midnight sun, and moonlight, showing possibilities of development which very few professional photographers have yet realised.

Correspondence.

☞ *Correspondents should never write on both sides of the paper.*

COLOURED LANTERN POSITIVES.

To the Editor.

Sir,—In your issue of March 4, you say that "M. Louis Ducos du Hauron writes to a French contemporary to point out that F. E. Ives' method of obtaining coloured lantern positives by superposition of different coloured pictures was anticipated by himself and M. Charles Cros so long ago as the year 1869. He therefore claims that it is a purely French invention, which has only been copied in America."

Has M. Louis Ducos du Hauron been asleep for the past ten years? Can it be that he has not learned that the method claimed by himself and Cros might, with very much better show of fairness, be credited to Henry Collen, of England, than my own method to himself or Cros? Composite heliochromy was neither invented nor carried to a successful issue in France, and the reproduction of such statements as the above is calculated only to deceive the public. The facts are clearly stated in my lecture on "Photography in the Colours of Nature," which was reprinted in your columns last year.

Vogel in Germany, Scott in England, and Bierstadt in America have also claimed the credit of my success, but they are all labouring under a delusion, or worse. The fact that we all use selective colour screens, and make three or more negatives of each object, does not make our processes the same, not even in the principle of colour selection, which, except in my own process, has always been absolutely inconsistent with the facts which support the modern theory of colour vision. In the interests of scientific progress among photographers, it is to be hoped that the persistent misrepresentation of facts in connexion with this subject may be discontinued.—I am, yours, &c., Fred. E. Ives

Philadelphia, March 15, 1892.

RATIO OF GRADATION.

To the EDITOR.

SIR,—I have been much interested by Messrs. Hurter & Driffield's reply to my letter of the 7th inst. in reference to the relations between the amount of silver and transparency in photographic negatives. I was certainly under the impression that the explanation of these relations, given in the first part of the paper on *Photo-chemical Investigations*, was intended as a mathematical demonstration of the truth of the views then put forward. Messrs. Hurter & Driffield, however, it appears, depend more on their experimental results than on the soundness of the reasoning there employed. That the formula $T = e^{-x}$ will not apply to every case in which light is obstructed by particles of appreciable size will, I think, be admitted, as it clearly fails in the instance I gave of a layer of only the thickness of one grain; and what we have to settle is, under what conditions does it cease to be trustworthy? In criticising my suggested formula, Messrs. Hurter & Driffield have understood a to mean the area covered by the reduced silver in each layer. It certainly always varies proportionately to that, but I used it to represent the amount of *light absorbed* by each layer in a unit of area. They consider that my reasoning necessarily assumes that the particles of silver are opaque, and would fail if it should prove that they only partially absorb the light falling on them, but I do not see that it would be affected if that were so. It is perfectly true, as they point out, that the particles in the second layer *might be so arranged* that $(1-a)$ of the light having passed the first layer, anything from $(1-a)$ to $(1-2a)$ might be the intensity passing through both; but we are dealing with very large numbers of grains of silver, scattered by *pure chance*, so that if we follow any one ray of light, whether through a clear part of the first layer or through a particle of silver, by which we will suppose its intensity is only partially reduced, then, in either case, its chance of striking a grain of silver in the second layer is precisely the same as it was in the first, so that we may reasonably conclude that the whole volume of light passing the first will be diminished by the second in just the same proportion as before; that is, it will then become reduced to $(1-a)^2$, and the same will be true till, after the nth, we shall have $(1-a)^n$ of the original light. Of course, as Messrs. Hurter & Driffield point out, the grains of silver in a photographic plate will not actually lie just in the n imaginary planes into which I have supposed the film divided; they will be more or less between one plane and the next; but, as this displacement can in no case amount to more than one-half of the diameter of a grain, so trifling a difference in position from that assumed in the reasoning could surely result in no appreciable error. In their explanation of the method by which their formula is arrived at, Messrs. Hurter & Driffield have to disregard differences from the theoretical position, sometimes amounting to many times the whole thickness of the film.

So far as these matters can be settled by reasoning, I think my views have some advantages over Messrs. Hurter & Driffield's; but the object of my letter was rather to show that there were apparently too many doubtful features about a photographic plate to allow of any really trustworthy result being so obtained, and I now gather from Messrs. Hurter & Driffield's article that they are nearly of the same opinion. It is claimed that experiments have shown, although the truth of it cannot be mathematically demonstrated, that density *is* proportional to the amount of silver; but this conclusion has been first led up to by reasoning to which, I have endeavoured to show, there is some objection. Now, my doubts as to the uniform correctness of that rule depend upon conditions which only exist, to any considerable extent, in the case of rapid plates. The close agreement between the ratios of the quantities of silver present and the densities, in the two experiments given by Messrs. Hurter & Driffield, is remarkable, and I was much struck by it when the experiments were first published; but still, if, as is probable, Chapman's slow plates were used, that does not show that Hurter & Driffield's formula, and not Plener's, was the only applicable one, because, in that case, both formulæ would probably have given identical results.

Messrs. Hurter & Driffield refer to the results of hundreds of experiments; but, of course, it is only from those published that others can form an opinion. I do not find that any of those described in the paper on "Photo-chemical Investigations" clear up the point, and I do not understand that others were specially directed to this matter. As very slow plates were used, as a rule, in those experiments, it is probably only a comparatively small number of them which would bear on the point in question. Even rapid plates vary considerably in coarseness of grain. The method of reading results at densities, too, sometimes obscures rather serious differences. An instance of that appears in experiment 11. A plate, having three gradations, was cut into pieces, one of which was developed with hydroquinone for 2·5 minutes, and another for 7·5. On measuring the densities, the ratio of the 10 C.M.S. part, compared with the 40 C. M. S., was as 1 : 3 in the first case, and as 1 : 2·7 in the other, an apparently close agreement, and quite in accordance with the principles advanced. The 10 C.M.S. density of the denser piece was ·785; this, multiplied by three, would have been 2·355, instead of 2·120, the actual density of the 40 C.M.S. These figures represent transparencies of $\frac{1}{147}$ and $\frac{1}{132}$, so that the actual transparency of the longer-developed piece was, after all, 1·9 times too great as compared with the other.

Against the experiments of Messrs. Hurter & Driffield we may, perhaps, set those of Captain Abney, which I mentioned in my previous letter. In order to test his formula, he experimented with Indian ink, suspended in varying proportions in water, doubling the quantity each time. He tested the opacity by saturating slips of white blotting-paper with each mixture, and measuring the transparencies when dry, and the result was that the figures were in very close agreement with his "law of error" formula; but I find they do not give the least support to Messrs. Hurter & Driffield's views. Thinking, however, that that plan might perhaps be open to question, Captain Abney undertook another experiment, just on the lines of the second one described by Messrs. Hurter & Driffield. A number of gelatine films were prepared, all of equal thickness, and each containing known quantities of finely divided silver, each of the series containing double the quantity of the previous one. The following table shows their transparencies, as found by Captain Abney, and also as they should have been if calculated by the "law of error" formula, to which I have added the densities which would result from his figures. The transparencies probably represent percentages of the original intensity of the light. At any rate, the plain film is given as having a transparency of 73, so that the other numbers must be divided by that figure to give the transparency, to one unit of light, of the *silver* contained in each film. The logarithms of the reciprocals of the fractions so obtained are the figures I have given in the "observed density" column. These, by Messrs. Hurter & Driffield's principles, should progress by doubling each time; but it will be seen that, except in numbers 2, 3, and 4, there is no appearance of such relations between them. In the "calculated density" I have shown the figures as they should be if the assumed equality of ratios between density and amount of silver held good; and in the last column are given the amounts of silver which would be found from Abney's results if calculated on that basis. For these columns I have taken line number 3 as the starting point, as that seemed the most favourable.

Number of film.	Amount of Silver.	Abney.		Hurter & Driffield.		
		Observed Transparency.	Calculated Transparency.	Observed Density.	Calculated Density.	Calculated amount of Silver.
7	64	1·0	1·1	1·863	5·048	24·0
6	32	3·5	3·4	1·319	2·524	16·7
5	16	9·0	8·7	·909	1·262	11·5
4	8	19·0	19·0	·584	·631	7·4
3	4	35·3	34·0	·3155	·315	4·0
2	2	50·6	52·0	·159	·158	2·0
1	1	67·0	67·0	·037	·079	·5
0	0	73·0	73·0	·000	·000	0·0

This experiment favours the view that it is the "law of error" formula, and not that of Hurter & Driffield, nor, I may add, that of Plener either, which gives the truest results; but the fact that we find so much difference in the results arrived at by competent experimenters appears to prove that it is not safe to trust entirely to any yet published formula. Messrs. Hurter & Driffield do not depend on any exact mathematical demonstration, but on the results of experiments, and here we have an experiment which is quite inconsistent with their views.

I had not overlooked the paragraph in the original paper to which Mr. Phillips calls attention, but I understood the writers to refer to the possible errors which might arise from varying colour absorption and reflection, and did not think it would affect my case that the *size* and position of the grains had been insufficiently regarded. Mr. Phillips will find that Captain Abney's paper on the "Law of Error" is given in THE BRITISH JOURNAL OF PHOTOGRAPHY of the 10th and 17th of May, 1889, another paper, dealing with intensification, appeared on the 29th of November of that year. These also appeared in the *Photographic News*. Captain Abney also read a paper on the subject at the British Association, in which he described the experiments to which I have referred. That paper was given in the *Photographic News* of September 27, 1889.—I am, yours, &c.,

H. J. CHANNON.

Blackheath, S.E., March 21, 1892.

DEPTH OF FOCUS.

To the EDITOR.

SIR,—I am quite willing to accept the definition given by Mr. Bennett of equal depth of focus. From this, together with the fact that the circle of confusion is proportional to to the focal length, his theorem follows at once. Mr. Bennett appears to have forgotten that, in his article of March 11, he professed to prove his theorem by showing that the two lenses would give *equal* circles of confusion, from which it would have followed from his present definition, that they had not the same depth of focus. However, that calculation was erroneous, as I showed last week, and I now admit that the theorem is established, assuming the meaning of the expression "depth of focus" to be as given by Mr. Bennett.—I am yours, &c.,

CLIFFORD E. F. NASH.

Cheltenham, March 28, 1892.

Answers to Correspondents.

All matters for the text portion of this JOURNAL, *including queries for "Answers" and "Exchanges," must be addressed to* "THE EDITOR," *2, York-street, Covent Garden, London. Inattention to this ensures delay. No notice taken of communications unless name and address of writer are given.*

**** Communications relating to Advertisements and general business affairs must be addressed to* "HENRY GREENWOOD & Co.," *2, York-street, Covent Garden, London.*

PHOTOGRAPH REGISTERED:—

Thomas Protheroe, Bristol.—*Photograph from an oil painting of Right Hon. W. E. Gladstone, M.P.*

E. J. SMITH.—About eleven o'clock any morning.

ALLISON BROS.—We do not know of any such list.

O.—The new platinotype paper is not yet obtainable commercially.

ZINCO.—Mr. Paul Waterlow treats of the subject in a lecture which we have in type.

G. JONES.—Substitute for the lens nearest the picture one of much shorter focus, by preference a crossed lens.

INQUIRER.—Avoid leather washers; soft metal ones are recommended by many authorities since recent accidents.

A. R. WOOD.—The Photographic Convention is to be held in Edinburgh during the week commencing July 11 next.

W. J. REED.—1. We do not understand this question. 2 and 3. Probably caused by keeping the paper in too dry a state.

H. J. DALBY writes in appreciation of Mr. H. W. Bennett's "thoroughly practical, useful, and easily understandable article on lenses."

E. D.—1. A slow plate and any of the pyro developing formulæ given in the ALMANAC. 2. Instructions for silvering glass are also given therein.

H. H. S.—The metal rims, glasses, and backs for the so-called "opalines" may be obtained from any of the large dealers in photographic materials.

LUX.—The prisms of a stereoscope will, if mounted in the reverse way—that is, the thinner edges to the outside—answer well for a binocular lanternoscope.

ILIAD.—There is nothing novel in the idea of using weak bromide prints as the bases of coloured pictures. Whether you could hope to make a financial success of it, however, is more than we can say.

CAMERA.—1. Yes; we believe the paper is excellent. 2. Most probably such an opening exists, but we do not think that at present a very large trade is to be done in ready sensitised paper in the colonies.

T. PULLING.—Yes; sulphite of soda may be employed as a fixing agent in place of hypo for silver prints, but the advantage of the exchange is doubtful, while, of course, it would involve greater expense.

JAMES E. GOOLD.—No English work is published on the Woodbury process. The process is fully described in the last edition of Hardwich's *Manual of Photographic Chemistry*. "Woodbury-gravure" is not patented.

S. W.—A lantern with a five-inch condenser will be of no use for enlarging with from 5×4 negatives; that is, if all the subject has to be included. If it has, nothing less than a six and a half inch condenser will suffice. The portrait lens will be preferable to the "rapid" as an objective.

RONALD C.—You have misread the instructions, no doubt. The back lens of a portrait combination is of no use for landscape work. For that the front lens, with its convex side next the ground glass, must be used. Simply remove the back lens, and screw the front one in its place in the position mentioned.

J. A. WHETMAN.—With a lens, the back and front combinations of which are identical, it matters not which way the instrument is placed with regard to the negative in enlarging; but, with a portrait lens, it is imperative that the posterior combination be next the negative in order to get the best results.

M.—The pigment with which the mounts are surfaced, or the medium with which it is mixed, is soluble in water, hence the wet print, when applied, dissolves it, and thus becomes stained. Wet the mount with water, and rub it with a piece of white rag, and you will find the whole of the "enamel" can be removed.

B. H. W. asks, if prints were coated with collodion it would not prevent their fading.—Experiment has proved that it does not. To an extent it may by protecting the image from the atmosphere; but if the prints contain within themselves the elements of decay, no outward application will prevent their fading.

ALBERT LEVY (Paris) asks us whether a plate is more, or much more, sensitive to light whilst developing than in the dry state?—He holds that it is, but we believe that the contrary has been determined. As to whether a plate is more sensitive "during the first second's exposure than during the second second's," and so on, we should say decidedly so.

DUNCE.—1. There is no other way than by dividing the equivalent focus of the lens by the diameters of the stops, the quotients being the apertures in relation to focus. 2. By applying the foregoing rule, you will see that the largest stop is considerably smaller than *f*-8, its aperture being approximately *f*-11½. 3. Any of the stops may be "a working stop."

A. CORNELL.—Your difficulty in getting sufficient density in the negatives when copying engravings to print black and white, is that you have been using about the worst kind of plates possible, that is, extra rapid ones. The best plates for the purpose, next to wet collodion, are the slowest plates. Plates such as those specially prepared for photo-mechanical work give the best results for this class of work.

OMEGA.—It will be very difficult, we imagine, for you to get a complete set of this JOURNAL from the first volume, as there are not many in existence. The only way is to advertise for one, or, failing to obtain it, advertising for odd volumes. By this means a complete set may be secured. The same with the other work.

B. SEAGOOD says: "I have for some time past been attempting to work photo-lithography, and have tried several of the published methods of working, but cannot succeed. My difficulty is that after the transfer is inked up, the ink cannot be got away from the white portions, even with rubbing. What can be the cause?"—The reason may be that the bichromated paper has been kept too long before use, or possibly the negatives are not dense enough, or the printing is carried too far. These conditions are probably the root of the difficulty.

RECEIVED:—R. C. Phillips and Albert Levy. In our next.

MADDOX FUND.—Additional subscription: Lewes Photographic Society, 1*l.* 1*s.*

THE date of publication of the *International Annual of Anthony's Photographic Bulletin* has been altered from June to December.

THE Exhibition of old silver prints, now on view in the rooms of the Photographic Society of Great Britain, will remain on view till April 12.

PHOTOGRAPHIC CLUB.—April 6, Dark Room Appliances, and paper by Dr. Jeserich on *Photography as Applied to the Detection of Crime*. 13, *The Choice of Lenses*, Mr. J. Traill Taylor.

THE Catalogue of the Camera Club Exhibition of Members' Work is a most artistic production, worthy of preservation as a souvenir. From it we learn that there are 86 exhibitors and 236 exhibits.

LONDON AND PROVINCIAL PHOTOGRAPHIC ASSOCIATION.—April 7, *Collodio-bromide Emulsion*, Mr. Alexander Mackie. 14, *The New Platinotype Paper*, Mr. W. H. Smith. 21, Dr. Jeserich's paper on *Photography and Crime*, illustrated by slides; also Indian and Colonial slides. Visitors are welcomed.

BRITISH ART PHOTOGRAPHY.—King Leopold opened the Exhibition of British Art Photography at the Cercle Artistique, Brussels, on Saturday last. His Majesty was accompanied by his nephew, Prince Albert, and a numerous staff. Several of the Ministers and a large number of the British colony were also present. The King made a minute inspection of the various specimens, and complimented several of the exhibitors, whose names we have already given.

AMONG the pictures shown at the last meeting of the Vienna Club of Amateur Photographers, and that of the Vienna Photographic Society, those of Mr. T. S. Bergheim and Baron Albert Rothschild excited particular interest. Bergheim's portrait studies and groups (scenes from the seraglio) received unstinted praise even from eminent painters. It is to be noted that he takes his pictures indoors, and uses ordinary uncorrected lenses for his portrait studies. Baron Rothschild displays so much earnestness, knowledge, and artistic perception that he could at any moment make his living as a professional photographer did he not prefer the lucrative position of chief of the great Vienna banking house.

PHOTOGRAPHIC SOCIETY OF GREAT BRITAIN AFFILIATION.—Meeting of Delegates, March 21, Mr. W. Bedford in the chair. Present:—Messrs. A. Mackie (North London P. S.), J. J. Thornton (Southsea A. P. S.), A. J. Golding (Holborn C. C.), P. Everitt (London and Provincial P. A.), C. H. Desch (Finsbury Technical College P. S.), E. W. Parfitt (North London P. S.), S. Hodsoll (North Kent P. S.), F. W. Pask (London and Provincial P. A.), J. W. Marchant (North Middlesex P. S.), F. W. Cox (North Middlesex P. S.), W. White (Ealing P. S.), A. F. Taylor (Ealing P. S.), Robert Steele (Leeds P. S.), F. P. Cembrano, jun. (Richmond C. C.), T. A. Pope (P. S. of India), C. C. H. D'Aeth (Dorset A. P. A.), G. L. Addenbrooke (P. S. G. B.). The Chairman announced that, by permission of the President of this Society, Dr. Jeserich's paper had been put in circulation, but the subject of circulating advance proofs of papers was in the consideration of the Council. Mr. Addenbrooke explained the decision of the Council as to the funds that were to be placed at the disposal of the delegates. After considerable discussion, Mr. P. Everitt moved that the Council be invited to confirm their resolution as applying to the current year only. Mr. R. Steele seconded this motion, which was carried. The advisability of appointing an Executive was then considered, and it was finally decided not to appoint an Executive but to delegate the work to sub-committees. Mr. Everitt inquired whether there was any prospect of special lectures being given, when a long discussion ensued, but nothing was decided upon. Finally, Mr. Cox moved that a London Sub-Committee be appointed to carry on the work till the next meeting of delegates. This was seconded by Mr. Steele, and it was decided that the existing Committee, consisting of Messrs. E. Clifton, P. Everitt, A. Mackie, and T. A. Pope, should form the Committee. Mr. Addenbrooke moved the addition of Mr. Bedford; this was seconded by Mr. Mackie, and carried.

JOURNAL OF PHOTOGRAPHY.

No. 1666. Vol. XXXIX.—APRIL 8, 1892.

STEREOSCOPIC PICTURES WITHOUT A STEREOSCOPIC CAMERA.

Because this article is written in the interests of the large class of photographers who are the possessors of only single cameras, let it not be thought that we are indifferent to the great importance and advantage of employing binocular cameras for purposes of stereoscopic photography. We ourselves invariably employ a camera of the latter class, the one we use being what is known as double quarter-plate size. Ordinary half-plate, or even 8 × 5 cameras, also answer well, it being assumed that a pair of similar lenses and a division in the camera are employed.

We have on former occasions stated, as the paramount condition on which stereoscopic pictures must be obtained, is that of two different points of sight being necessary for each picture. These points need not necessarily be far apart, a distance of even so little as one inch, under exceptional circumstances, up to three inches sufficing.

If a camera be fixed upon its stand by a screw, not close to the front, but nearer to the back of the camera, and a picture be taken, the mere act of rotating the camera on the stand to a very slight extent will cause a displacement of the lens from its original position to one which may, according to the size of the camera and the position of the centre of rotation, vary to one, two, or more inches from the original position. In the pictures taken with each position there will be much in common. One will have at its margins some subjects not to be found in the other; but, when such portions of the scene as are embraced are compared, they will be found to be identical, yet different—identical as regards the subjects themselves, yet different in regard to the relation of one part to the other. This subject cannot well be elaborated in an article so brief as we purpose the present one to be, but the thoughtful photographer—and we gladly recognise many such among our readers—will not fail to appreciate its possibilities in this direction.

It involves, and so do other systems to be described, the non-simultaneity of both exposures. Good friends, we have not in our mind's eye, at present, instantaneous views of street scenes, boating or horse races, but those of quiet life, in which figures in the foreground are an unrecognised entity; these latter must be taken by a binocular instrument.

But if, by a little forethought, the photographer has considered the propriety of having attached to his camera stand a scale of, say, ten or twelve inches length, to which he may slide his camera from side to side, in order to obtain pictures from the various points of view requisite to give stereoscopic effect, then is the condition equally well fulfilled.

It is the relation of the point of sight to the sitter that determines stereoscopic relief. If a subject, when photographed—the camera being fixed at a definite point—be then rotated in even the slightest degree and then photographed; then will two pictures taken under these different conditions be different. We have elsewhere stated that a stereoscopic photograph of a subject, such as a human figure, a pot of flowers, or similar object, may be obtained if the subject be rotated ever so slightly between the first and second exposure. Let a sitter be placed upon one of the office chairs, the seat of which rotates upon a central axis, like that of a piano stool. After the first picture has been taken, let the chair be rotated in the slightest degree, and a second picture be then taken. The sitter, of course, must remain perfectly still while the rotation is being made and a second plate inserted and exposed. Care must be taken that the rotation is not carried too far, else will a too-exaggerated degree of relief be the result. Let it be noted that the stereoscopic effect in this experiment is confined to the sitter only in relation to each part of himself, and not to that between him and the background, which ought, in this case, to be quite a plain one.

PHOTOGRAPHING ON WOOD.

That it should have received the commendation of several wood engravers and others professionally interested in the subject, who were present when Mr. W. J. Rawlings demonstrated a process of printing photographs on wood for engraving purposes, before the members of the London and Provincial Photographic Association last week, is, perhaps, the best praise that could be bestowed upon the method, which will be found described by himself in another part of the Journal. Some of the salient points of the process, however, strike us as being so useful that we shall here take occasion to particularly indicate them, not less in recognition of their practical value than as conveying an idea of the variations upon older methods which Mr. Rawlings has introduced.

Mr. Rawlings first prepares the surfaces of his blocks with a mixture of zinc-white and albumen, which, besides serving the useful end of giving a white ground to the finished picture—a great convenience, we should think, to the engraver—also, if we mistake not, fulfils other functions in the course of the process, one of them possibly being, as was hinted at the meeting, to enter into combination with the silver nitrate of the sensitising solution to form silver carbonate.

When the surface of the block is ready for sensitising, silver nitrate in plain collodion is applied to it, and, this film having

been dried over heat, the collodion is removed by ether and alcohol. The sensitising operation is then repeated, and the second film of collodion also removed, thus leaving the block sensitised with a mixture of nitro-carbonate of silver on zinc-white and albumen. The sensitive surface, which is said to be about as rapid as albumen-silver paper, is then ready for printing under a negative in which the right and left sides are reversed. For small blocks Mr. Rawlings uses clips for holding the negative and block in contact, and for large ones a frame of special construction.

Up to this stage no water has come into contact with the block, and indeed it is possible by a little dexterous manipulation to retain whatever aqueous solutions may be employed entirely upon its surface. The picture when printed out is fixed by hyposulphite of soda in the proportion of six ounces of the salt to twenty of water, an operation which Mr. Rawlings performed by simply flowing the solution over the surface of the block in the manner in vogue with cyanide fixing of wet plates. The picture is then washed by directing a stream of water upon the surface for fifteen seconds, and, after having the free moisture removed, is dried over heat and is then ready for cutting. In that condition it forms, it is said, an admirable surface for the engraver's work, and, moreover, freely allows of the use of the pencil in alterations.

The preparation, sensitising, and printing of a block on the occasion referred to, and indeed the whole process, was completed in a very few minutes. We gathered that it was possible to produce a block ready for the engraver in about an hour from the time of taking the reversed negative. The washing of the latter is, of course, largely shortened, while drying, according to Mr. Rawlings' plan, is effected most expeditiously by squeegeeing off the surplus moisture with the thick part of the hand, and completing desiccation by heat. It will be remarked that the pictures are not toned, while their perfunctory washing and fixing is, of course, dictated by an absolute disregard of the dread of fading. The second sensitising of the block, according to the opinion of the originator of this method, gives better results than would be obtained by simply applying a single solution proportionately stronger in silver nitrate.

The process appears to be perfectly adapted for the purposes of engraving line subjects on wood, and, by what we could deduce from the remarks made on the occasion of the demonstration, will be welcome to wood-engravers generally. Not the least pleasant feature in connexion with the process is the freedom with which its sponsor has published and demonstrated its capabilities. We are glad to find that Mr. Rawlings' action in this respect met with very cordial recognition from those who witnessed the demonstration, the most prominent in acknowledging the boon being those who will be benefited by the particulars of the method given.

Having regard to the interest which the subject excites, it may be fitting that we should seize the occasion to outline some of the older methods of photographing on wood which have been found to answer the purpose. In the first of these the surface of the wood is treated with finely powdered white lead and a little water, and, when dry, is coated with a weak solution of mastic and guttapercha in benzole, consisting of three grains each of the two first-named in an ounce of the solvent, which does not leave any film on the wood, but serves to fix the white pigment. The whites of several eggs having been beaten to froth, and salted with four grains of chloride of sodium and eighteen minims of strong ammonia to each egg, is kept in a warm place for about a month, water being added to make up for the loss by evaporation, and after filtration is applied to the block with a brush. When dry, the surface is sensitised with a forty-five-grain silver solution, also by means of a brush. The operations of printing, fixing, and washing are needless to describe.

Besides the collodion transfer system, which is probably thoroughly familiar to most wood-engravers, and which, therefore, on the present occasion we shall not treat of, it is perhaps not so well known that the carbon process may be adapted for the purpose. In this a specially prepared tissue is necessary, and when sensitised a print is taken under the negative in the usual way. The face of the wood having been slightly gelatinised, the print, after being immersed in cold water, is squeegeed face downwards in contact with the block. The paper is stripped from the gelatine in warm water, and development of the picture is then proceeded with until all the details are visible. In this method a reversed negative is, of course, not required.

It will be remarked that in the method described by Mr. Rawlings the collodion film is removed before exposure; but in that now about to be mentioned and previously published elsewhere this removal is not effected until after the print is made. The method in question is that of applying a mixture of silver and uranium nitrates in collodion to the surface of the wood. Two ounces of ether and four ounces of alcohol, saturated with nitrate of uranium, are mixed with two ounces of alcohol in which thirty-two grains of silver nitrate have been dissolved. The mixture being filtered, fifty grains of soluble cotton are added, and after dissolution, and settling in a dark place, the collodion is ready for use. This is applied to the previously prepared surface of the wood, and the print made by contact. Fixing is accomplished by a dilute solution of ammonia, and when dry the application of a mixture of ether and alcohol removes the collodion film, and leaves the picture in the wood itself.

Both the collodio-chloride emulsion and blue printing processes are applicable to the production of photographs on wood, but enough for the present has probably been said to indicate the considerable variety in the methods of working which are available. Some of these, as well as others not now touched upon, may form the subject of a more detailed descriptive article at some future time.

Photographers' Half-holiday.—We understand, from a communication in a local paper, that the Greenock firms of photographers have agreed to close their places of business on Fridays during the season at two o'clock in the afternoon. Considering the long hours which most assistants have to work in the summer months, this example is worthy of imitation.

The Paris Photographic Exhibition.—This Exhibition, which opens in the course of the present month, as already announced, has received support from most European countries, as well as from the United States. We are not told to what extent English exhibitors have contributed. While the Exhibition is open there will be as additional attractions frequent balloon ascents. We hope a batch of successful balloon photographs will result. By the way, we observe that France during this year is to suffer from a serious outbreak of "the international exhibition disease," such as we had in this country the last and preceding years, many large French Societies having decided to cover themselves with glory in this manner. Here the idea has been rather overdone, and we are glad that this present year of grace is to be a quiet one from an exhibition point of view.

Cause of Streaks and Tears in the Wet Collodion Process.—Those of our readers who use, or who have used, the wet-collodion process, know the extraordinary way in which the surface solution behaves when the plate is withdrawn from the bath. For no apparent reason streaks and tears of liquid form or patches come upon the plate where the liquid is quite driven away. The cause, or one cause, of these appearances is shown in a very pretty lecture experiment illustrated in a recent number of *Nature*. We need not reproduce it here, but will simply explain that a drop of water is caused to form at the end of a pipette, and there remains adherent to its point, when, upon a quantity of ether being brought into proximity, the following phenomena present themselves, and fully illustrate the action of the bath solution we speak of. "As the ether is brought up, the absorption of its vapour diminishes the surface tension over a small area of the drop of water, and currents, made visible by suspended dust, appear to pass from the interior towards the weakened spot. Bringing the ether still nearer, the drop often becomes much agitated, and finally, when the distance is reduced to about 4 mm., it falls away from the tube." We have often performed a still simpler experiment which can be repeated without any apparatus. Bringing the mouth of an open bottle of ether towards the surface of a perfectly wet negative, the surface liquid will be caused to recede and leave a portion of the negative almost dry in comparison.

Private Stills.—It is generally understood that no photographer—nor, indeed, any one—can keep a still, even for distilled water, without first obtaining permission from the Inland Revenue authorities; but, in last week's *Chemical News*, Mr. Wm. Ackroyd, of the Borough Laboratory, Halifax, holds a contrary opinion. He writes: "The law regarding stills was never meant to apply to those in use in private laboratories or chemical factories. I was recently engaged in a case, Regina v. Illingworth, in which it was successfully contended by the defendant's solicitor that the intention of the Act is to prevent the manufacture of liquors which are illicit, and surely distilled water is not one of them! In the case mentioned, the Revenue people were attempting to impose a licence on a manufacturer who used a sulphate of ammonia still. The Bench of West Riding magistrates decided that 'this still is not within the meaning of the Act.'" This is all very satisfactory as far as it goes, but it goes to prove the view the Revenue authorities hold, and the user was put to the trouble and expense of defending a suit at law. Further, they appealed against the magistrate's decision, but the death of the defendant put an end to further proceedings. But there is more to be said. Messrs. A. J. Warren, makers of methylated spirits, write, in the same issue, to say that another correspondent "has legally incurred a fine through having a still on his premises without either having paid for a licence or having permission from the Board of Inland Revenue to use the same." His advice is to "address his request to the Commissioners of Inland Revenue, Somerset House, London, showing clearly that the still is used by him for chemical research. The Board of Inland Revenue are very ready to allow stills free of excise licence when it is proved beyond a doubt that they are wanted for purely scientific purposes; but *they must be asked permission first*. They have, in the last few month, also, to our certain knowledge, given permission to several directors of laboratories to obtain unmineralised methylated spirit. We have had no case of this kind refused, and have forwarded several applications on behalf of the heads of laboratories to them." Now, after these utterances, it is perfectly clear that any one endeavouring to use a still would be foolishly running the risk of incurring great expense, while, at the same time, a simple course is open to him of obtaining what he needs by the expenditure of a little time and a few sheets of paper. We have referred at length to these two subjects, as they are of great importance to many of our readers.

VARIATION IN COLLODION EMULSION WORKING.

So far we have spoken only of utilising spoilt or defective emulsions; but obviously, if the process recommended should prove to have any special value, the emulsion may be partially sensitised for the particular purpose; indeed, it would seem but natural that the better result would accrue from a preparation which had not developed signs of inherent weakness. However, as already stated, the defective emulsion is quite amenable to suitable treatment, all that is requisite being to free it from any traces of fog that it may have acquired, either from considerable exposure to strong light or from over-ripening in the absence of a sufficiency of acid or other restraining matter.

In addition—and this is more especially the case where a tendency to want of density exists—there must be an excess of soluble bromide of at least one or two grains to the ounce to combine with the silver nitrate to be afterwards applied. The only effect of applying a silver solution to a neutral and fully sensitised emulsion—to a washed emulsion, for instance, from which all soluble bromide has been already removed—would be to produce inevitable fog from much the same causes as those which prevail when fog comes from over-ripening. When the small proportion of free bromide is present, however, it is converted into silver bromide of the most rapid, as well as density-giving, kind, and not only averts the fog, but confers those qualities in which the emulsion was previously deficient.

Supposing the emulsion to be only wanting in the capability of giving density, it is only necessary to supply the requisite quantity of free bromide, and the most suitable for the purpose is perhaps the ammonium salt. But should there be any fog present, as will almost invariably be the case under the circumstances, unless the emulsion has already been submitted to treatment as described in the previous article, it is essential that it be thoroughly cleared. Fortunately this is very easily done, though in the case of an ordinary emulsion it would be greatly to the detriment of its sensitiveness, or, in that of a washed emulsion, practically would destroy its sensitiveness altogether. It is merely necessary to add, in place of the bromide of ammonium, a corresponding quantity of the bromide of a dyad metal, such as copper, which is capable of acting directly upon the partly reduced silver that constitutes the fog, and reconverting it into normal silver bromide. Bromide or chloride of copper, as is well known, not only destroys the undeveloped image, but will reconvert the metallic silver forming the developed image into the condition of bromide, and in the same manner these salts act upon an emulsion in removing fog, though with a serious effect upon the sensitiveness of the preparation, unless very thoroughly removed from the film by subsequent washing.

Bromide of copper, or cupric bromide, is a very inconvenient salt to handle or to keep, on account of its instability. The chloride forms a more definite and stable compound, readily obtainable and easily kept, and might probably be used alone in place of the bromide. Where, however, it is not considered desirable to introduce chloride of silver into the film, the employment of cupric chloride cannot be recommended, except in conjunction with an equivalent of ammonium bromide, by which, of course, the soluble silver salt would be converted, leaving the cupric chloride free to exercise its clearing action.

A somewhat similar, if not identical, effect is produced by using ammonium bromide in the first instance, and afterwards shaking up with the emulsion a small quantity of finely powdered cupric sulphate—the ordinary "blue vitriol" of the shops. By this method of treatment the ammonium bromide is decomposed cupric bromide, and ammonium sulphate being formed, and any excess of the sulphate, being insoluble, remains to be filtered out.

Still another, and perhaps the best, plan, all things considered, is to prepare an alcoholic solution of bromide of copper, and to estimate its value volumetrically in order to avoid the inconvenient process of obtaining the salt in the crystalline form. In alcoholic or ethereal solution the salt appears to keep very well. We have kept it without appreciable change in this manner for several months; but any application of heat or other means of evaporation almost invariably decomposes some portion of it. When the solution is once obtained and approximately estimated—for this purpose analytical precision is quite unnecessary—it will retain its qualities for a long time, and so many minims may be taken as representing so many grains.

To prepare the solution of cupric bromide, weigh out equivalent proportions of bromide of ammonium and sulphate of copper, both finely pulverised and carefully dried. The latter salt in its crystalline state contains a certain proportion of water of crystallisation, which may be driven off by exposing the powdered crystals to a gentle heat if prolonged for a sufficient time, the result being a perfectly white powder. This treatment is not absolutely necessary, but it is to be

preferred. The proportions of the respective salts will be four parts by weight of ammonium bromide to five of crystalline cupric sulphate, which may be powdered and dried after weighing. The two are then mixed thoroughly in a glass mortar, or other convenient vessel, when if any moisture be still present, a green colour will be developed; but, if quite dry, nothing beyond a slight greyness is produced. Next pour on a small quantity of strong alcohol—we prefer the pure absolute alcohol, though an inferior grade will answer—or sulphuric ether, the cupric bromide being very soluble in either liquid, when a deep brown, almost black, solution will be instantly formed. Cupric bromide, like many other salts, exhibits dichroic properties, according to whether moisture be present or not. In aqueous solution, or when an appreciable quantity of water is present, the colour is green; but in alcoholic or ethereal solutions it exhibits a variety of tints, varying from lemon-yellow to nearly black, according to the degree of concentration and other circumstances.

Pour off the first quantity of alcohol as closely as possible, and apply a fresh lot, repeating the process until nothing remains but a colourless or slightly grey powder; then make up the volume of the solution to something having a definite relation to the quantity of bromide used in the first instance. Thus, if 100 grains of ammonium bromide were used, and the volume be made up to one ounce, every five minims will represent, as nearly as possible, one grain, and if, on testing the solution, that be found to be approximately correct, it will be quite near enough for our purpose.

Whichever method of forming the cupric salt is adopted, it is desirable to allow the emulsion to rest for at least twenty-four hours after its addition, as the action proceeds rather slowly in the attenuated state of solution. In cases of very bad fog a much longer time may be required, but we have never known a case of fog so bad that t would hot eventually succumb to this treatment. When the emulsion has been once cleared in this manner, it will remain in good condition indefinitely, or, at least, its lease of life is dependent rather on its organic constituents than the inorganic; that is to say, the pyroxyline may become decomposed by age, and the emulsion lose its power of suspending the silver bromide, but the latter will not lose its useful properties. This addition of a cupric haloid, in fact, constitutes an admirable means of indefinitely preserving an emulsion when, as in the present instance, extreme sensitiveness is not required.

If the emulsion in its present condition be spread upon glass, washed until the volatile solvents have been removed, by which time the remaining soluble constituents will have been practically removed also, it will be found, though slow, to give a beautifully clean image. If it should happen to be an emulsion that has undergone this treatment owing to its want of density, that defect will still remain; for the rebromising has no power to increase the organic properties of the emulsion. If, on the other hand, the emulsion is freshly made from perfectly suitable materials, the probabilities are that the character of the image will be the very reverse as regards vigour; that is to say, if a sufficient exposure be given, the density and contrast will be such as to render the emulsion particularly suitable for photo-mechanical work. Even when it does not run particularly to density, the beautiful clearness and absence of fog or veil will recommend the films, especially for the production of lantern slides by contact. For camera reduction, the exposure required would, in most cases, be too long.

It may here be remarked that it is useless to attempt to expose the plates previous to washing, as, until the soluble salts are removed, the films are practically quite insensitive to light, even full daylight. We have purposely exposed a coated plate to diffused daylight, subsequently washed and exposed it in the camera, producing an image of the most irreproachable clearness. It is hardly necessary to add also that the emulsion itself is even less affected by light, for, even if its outer surface layer were actually discoloured, the cupric salt present would, in a very short time, restore it to its original state.

The emulsion is not, however, primarily intended to be employed in this state, but to be first treated with a solution of nitrate of silver. This may be of any convenient strength from ten grains upwards, the sensitiveness of the resulting plates depending, in some measure, upon the quantity of silver present. A five-grain solution may be used if a comparatively slow plate will satisfy; but with this feeble bath there is a tendency to want of vigour. Ten grains to fifteen we consider the best strength for general purposes, but it may be increased up to thirty or forty grains where very rapid films are desired, or where more than the excess of bromide we have given is used. There is, however, in our opinion no adequate advantage gained by going above fifteen grains.

With regard to the preparation and use of the silver bath, none of the precautions surrounding the old silver bath are needful. The silver is simply dissolved in ordinary water and filtered. It is necessary to apply it in a dish or other vessel, owing to the impossibility otherwise of applying it uniformly to the surface, as necessarily the silver bath must be applied before the plate is washed. It is not necessary to acidify or otherwise add to the solution, nor does it appear essential that the bath shall be absolutely kept for this one particular purpose, a sensitising solution for albumenised paper, for instance, having given perfectly satisfactory results. In point of fact, the copper salts employed appear to exercise much of the functions of free acid, as observed by Mr. M. Carey Lea many years ago.

In the interests of uniformity of result, it is desirable, when this process is used regularly, that a considerable bulk of solution be employed, otherwise its strength will rapidly alter and irregularity ensue. Under such circumstances, nothing better than the old dipping bath could be used, but for occasional purposes an ordinary dish may be substituted.

(To be concluded.)

CAN SILVER PRINTS BE MADE PERMANENT?

The small collection of early silver prints now to be seen at the rooms of the Photographic Society of Great Britain, as we said last week, is both an interesting and instructive one. It is almost to be regretted the idea of getting together such a collection was not made more widely known, as, no doubt, it would have been more complete than it is. One thing that strikes the visitor on examining the photographs is, cannot something be learnt from them with regard to making our prints more permanent in the future?

For some years past it appears to be an almost recognised thing, both by the public and the profession, that silver prints must necessarily fade after a few years of existence, and so generally has this idea been accepted by most people that no attempt is now being made, or is, apparently, likely to be made, to improve matters. Indeed, we recently heard it remarked, in reference to this topic, that we were "going from bad to worse," as the majority of prints made during the last two or three years were fading in a shorter time than were those produced seven or eight years ago. Therefore, as a matter of fact, as regards stability we are retrograding.

It has been stated over and over again by theorists that silver prints cannot be made permanent; but, in face of this, there are now on view in the Exhibition some prints that were made in the early fifties which show no signs of fading proper. What slight change there may be in them is not greater than there would have been in engravings, had they been kept under analogous conditions. In fact, in some instances, it is less, particularly if the latter have been made on some of the papers now in the market and used for printing purposes, which rapidly become discoloured by exposure to light. In some of the exhibits the prints themselves seem to have suffered less than the mounts when they had been kept in the damp. In face of these, who will affirm that silver prints cannot be made, to all intents and purposes, stable?

If only one print in a thousand, nay, ten thousand, proves permanent, it establishes the fact that silver pictures do not of necessity fade; also, that if the others had received identically the same treatment in their production, and were kept under the same conditions, they should be equally as permanent. What are the conditions that have rendered one picture permanent while others are evanescent? Why have not all faded alike? That is the problem to be solved. In the collection are two copies of the *Photographic Album*, published in 1855. It is curious to see, in many instances, that the same picture in one book, and made presumably under the same conditions, and at the same time, as that in the other, has changed considerably, while the corresponding one in the other album has changed but little. On the other hand, some prints in one book have suffered more than

have corresponding ones in the other. This clearly shows that the difference, where it exists, is not due to the conditions under which the prints were kept, but to something in the manipulation in the first instance. The majority of the prints shown were toned and fixed at the same time in the old hypo and gold bath.

In the early days of the Photographic Society, when it had the energy of youth, it appointed a committee to investigate the whole subject of the fading of silver prints. The report issued by that body resulted in other methods of toning being sought for that would give a greater promise of permanency. Eventually the present system of alkaline toning was adopted, and that, it was then considered, would prove a panacea for the evil. This process has had a fair trial of over thirty years, with what result we are too painfully familiar.

Some persons have suggested during the past few years that, seeing the permanence of some of the early prints, we should go back to the old system of toning and fixing in one operation. This suggestion should not, however, be acted upon without due consideration, for there is no question that, theoretically at least, the present system ought to yield the more stable results. Another point is, that it is very doubtful if, with the present lightly sensitised and highly albumenised paper used with the thin negatives of the present day, such brilliant prints could be obtained as by the process now in vogue.

It is to be regretted that the subject received so little attention the other night from the members of the Society and others interested in photography. The question of the permanence of the prints is, or ought to be, one of the most important matters in the photographic world, for there is no doubt that the process has yet to be invented that will supersede silver prints for general every-day work. Hence, for the credit of the art, they ought to be made reasonably permanent, and, in face of examples before us that have endured for something like forty years, it is undeniable that they may be.

Would this topic not be a suitable one for discussing at the next Photographic Convention, or at a general meeting of the Photographic Society, seeing that that body is now more inclined to deal with purely technical matters than it has been hitherto? Possibly, under the affiliation scheme, other societies might be induced to associate and take up the subject generally.

CONTINENTAL NOTES AND NEWS.

Two New Developers.—A few weeks since we announced the imminent introduction of a new developing substance—metol. Two others are stated to have formed the subjects of some experiments by Herr Schmidt, of Frankfort-on-the-Main. They are, according to the *Correspondenz*, methyle-para-amidophenol-meta-kresol and para-oxyphenyl glycin—both derivatives of para-amidophenol. Happily, they are called, for short, methol and glycin respectively. They are employed in one-solution developers, and, of course, are very energetic. All new developers are!

The Aluminium Light.—M. Villon finds aluminium superior to magnesium, inasmuch as it burns slower and does not produce any smoke. The flame is also just as actinic. He has succeeded best with a lamp, into the centre of whose flame a jet of oxygen is passed, the powdered aluminium being then projected on to the flame in the usual way. He recommends the following mixture as giving a very powerful light:—

Powdered aluminium	100 parts.
Lycopodium	25 „
Nitrate of ammonium	5 „

Coloured aluminium lights for scenic purposes are obtained in the ordinary manner, that is, by employing the various salts of strontium, barium, copper, &c.

Sunday Photography in Germany.—Recent enactments have prohibited certain forms of labour on Sunday throughout Germany, which comprehends the practice of portrait photography. Whereupon the Hanover Photographic Union and the German Photographic Union have made long and strong representations to the Minister of Commerce and the Imperial Chancellor, stating the case on their own behalf as well as on the parts of their assistants and the public, and begging that the restrictions sought to be imposed on professional portrait photography on Sunday should be relaxed in the interests of all three classes. We have not heard the results of the appeals.

Copper-Uranium Printing Processes.—M. Letellier in the *Revue Photographique*, gives the following particulars for obtaining prints of a red tone:—Seventy-two grammes of nitrate of uranium and twenty grammes of nitrate of copper are dissolved in a small quantity of water, the solution being neutralised with carbonate of soda and made up in bulk to a litre. Paper sized with gelatine or arrowroot is sensitised in the solution for a minute or two, and dried in the dark. Printing is carried on until the image is faintly visible, when it is developed to its full intensity by an eight per cent. solution of potassium ferrocyanide. The picture is then washed and "fixed" in plain water. For sepia tones the uranium-copper solution is neutralised with ammonia, and the image is developed on a two to three per cent. solution of potassium ferrocyanide.

Development shown on the Screen.—M. Molteni, at a meeting of the Photo-Club de Paris a few weeks since, is stated to have thrown on the screen the image of a plate undergoing development. The exposed plate was placed in an upright (?) glass dish, containing the developing solution, in the position, we suppose, although it is not so said, usually occupied by the slide-carrier, so that, as we are told, the members could witness on the screen the growth of the image on the plate. The demonstration is said to have been successful, but we should like to have had a few more particulars; for instance, what was the colour and shape of the glass dish, and was the picture fogged or not? At any rate, if the idea is a practicable one, we hope to see it imitated in this country. In such a manner development could be demonstrated in the lecture-room, presumably in white light.

Kite Photography.—At the same meeting M. Londe exhibited a number of photographs taken from a kite by M. Wenz, of Reims, which are said to have been irreproachable. The apparatus can be employed either vertically or horizontally, and the shutter is controlled either by a time-match or by a current of electricity.

Experiments with Rapid Dry-Collodion Plates.—Dr. Miethe has been experimenting with Gaedicke's rapid dry-collodion plates, and has published the results, which are of considerable interest, in the *Wochenblatt*. Photographing a well-lighted view, and using a small stop, he exposed for four and two seconds respectively; using a large diaphragm, he took an out-door portrait in one second; copied an oil painting, with the smallest opening, in four seconds and two seconds. The exposures proved to be: No. 1, over-exposed; 2, about right; 3, slightly over; 4, over-exposed for the yellows; 5, correctly exposed. Development in all cases was completed with the properly exposed plates in about thirty seconds; with the others, in forty to fifty. He states that the orthochromatic effect obtained was very remarkable, the colours being reproduced according to their values better than they would have been on a plate treated with argentic erythrosine. The grain of the deposit appears under the microscope to be finer and more regular than that of gelatine plates.

Photo-micrography and Crime in France.—It must not be supposed that Dr. Jeserich, of Berlin, is alone in the application of photography conjoined to the microscope to the detection of documentary falsifications. In a recent number of *La Nature*, M. Albert Londe has an article, from which it may be deduced that French men of science and the State authorities are just as alive to the enormous advantages of photo-micrography as the coadjutor of justice as their eastern neighbours. M. Londe relates a case of fraud, detected by means of photography, such as Dr. Jeserich had no parallel for in his now well-read paper. It seems that in France gold rings are "hall-marked," so to speak, by being "punched" with very small and finely engraved marks and countermarks, representing, for example, horses' heads and insects. These last, in fact, constitute the

Havre marks, and, doubt having been cast upon the genuineness of those marks upon certain rings, the latter were placed in the hands of expert engravers, who pronounced the marks false. To make the falsity clear enough for a French jury, M. Londe undertook to take photo-micrographic reproductions of the engravings, both genuine and false, and, having done so, the comparatively small magnification of twelve diameters was sufficient to remove all doubt as to the fraud, the differences in fineness of the engraving being enormous. In this case photography supplied most valuable corroboration of expert evidence.

Orthochromatic Collodio-bromide Emulsion.—According to the *Rundschau*, Herr von Hübl's method is as follows: 40 grammes of silver nitrate are dissolved in 50 grammes of water, ammonia being added until the precipitate is redissolved. Thirty grammes of ammonium bromide are next, by the aid of heat, dissolved in 35 c.c. of water and 70 c.c. of alcohol. To 450 c.c. of a four per cent. normal collodion, the silver solution is added in the dark room. Disregarding the slight precipitates formed, the ammonium bromide, still warm, is added, the emulsion being well agitated. After the emulsion is washed and treated with alcohol to remove the last traces of water, it is dissolved in 400 c.c. each of alcohol and ether, 0·5 gramme of codeine added, and left for three or four days, when the eosine solution is added. The silver eoside is prepared as follows:

Eosine	10 grammes.
Boiling water	350 c.c.
Silver nitrate	5 grammes.
Water	50 c.c.

The precipitate is filtered off and allowed to dry in the dark room; 0·5 gramme of this silver eoside and 1 gramme of ammonium acetate are then dissolved in 20 c.c. of alcohol, and a mixture of 6 c.c. of acetic acid in 170 c.c. of alcohol added to it. To sensitise the emulsion one-tenth of its volume of the silver eoside solution just described is employed. Development may be effected either by hydroquinone or pyrogallic.

RATIO OF GRADATION.—III.*

The next experiments were in the direction of under-exposure, and from amongst several I select an exposure of three seconds, at the same distance from the lamp as before, to illustrate the behaviour under modified treatment. With the normal development, the first three tints only were produced, although the action was continued for some time after number three had become visible. Perhaps it was due to this continuation of the development to some extent that the density, especially of the first two tints, was very great, the third, though much thinner, being still very far removed from the clear glass representing the remainder of the scale. This exposure, it will be observed, was, with normal development, too short to reach the effective portion of the scale produced under the original and strictly normal conditions, the gradation in that instance commencing only when this last image ceased.

The comparison slip was developed in a solution of pyro and ammonia, in which all three ingredients were present in far smaller proportions than the ordinary, the alkali, however, being reduced to a less extent than the pyro and bromide. The exact composition of the developer with which the image was brought out was: pyro, one grain; ammonia, one and a half minim; and bromide, one quarter of a grain to each ounce. The intensification on the completion of the image was effected with a solution made up to the strength of three grains of pyro, three minims of ammonia, and half a grain of bromide to the ounce.

Upon the application of the first solution, the first three or four tints made their appearance without much delay, following one another in regular succession, but after the fourth there was a considerable interval—perhaps ten minutes—before number five became visible, and at this stage the three lower tints were undistinguishable, either by transmitted or reflected light. After another long interval, during which the fourth tint had become merged into the three preceding ones, and the fifth had gained in strength, number six became faintly visible, but after that a full half hour failed to bring out any more, though the last two tints gained slightly in strength. The more concentrated solution was then applied, and almost instantly the lower tints commenced to gain density, and, as previous experience had shown me, in proportion to the amount of the light's action they represented. The last two tints, but especially number six, were very little affected by the intensifier, although it was continued until it had produced its maximum effect on the lower tints, as was shown by number two becoming nearly merged into number one.

The final result was a scale of six distinguishable tints, the same number, in fact, as under normal conditions, although lower down on the scale. The contrast in this case between the highest and lowest gradation of the scale was greater than in the normal plate.

Now, looking at these results, it seems to me impossible to deny that the ratio of gradation has been altered, and that very considerably. In the comparison of the two over-exposures, we have eight tints, accompanied by increased contrast with the modified developer, as against only four tints with the normal; and, though I have not the means of accurately measuring the respective densities, to the eye there appears little doubt but that the difference between numbers nine and six—the limits of the scale of normal development—is decidedly less than that between the same numbers on the other scale. Again, in the case of the two under-exposures, the three tints representing the scale of the normal developer include a wider interval than the six tints of the other scale; that is to say, that visually the contrast between one and three in the first instance is greater than between one and six in the other. The ratio in this case can obviously not be the same.

Of course it is open to Messrs. Hurter & Driffield to contend that this mode of development is a departure from the ordinary course, and is therefore not included in their results. I am quite ready to admit this; but, as I have already said, my object is not to attempt to upset their deductions, but to show that the practical photographer has, to some extent, the power of modifying the rates of gradation in very extreme cases, although, perhaps, the method adopted may not strictly come under the heading of fair development. It may be at best but a subterfuge by which a passable result can be obtained where other means fail; but it is undoubtedly the case that the best results and correct gradation can only be secured with proper exposure and development. As regards what constitute the latter, there is sufficient latitude in both to permit of comparatively considerable variations without over-stepping the lines that divide a correct exposure from one that is incapable of giving a good result.

In conclusion, I regret my inability to give accurate measurements of the actual densities obtained, and, failing that power, it would be useless to attempt to establish any definite ratio between the tints of the scale used, which, accordingly, I have not attempted. But it seems to me that the results detailed above show conclusively, without figures or measurements, that the ratio is really altered.

W. B. Bolton.

PHOTOGRAPHING ON WOOD FOR ENGRAVING PURPOSES.

[London and Provincial Photographic Association.]

As photographing on wood is my subject for this evening, perhaps a few words will not be out of place on the art of drawing and engraving on wood. It is generally understood that for illustrating any journal, catalogue, &c., for printing type-high in the ordinary press, engraving must be resorted to in some way or another, either by wood-engraving, photo-zincography, or what is termed the half-tone relief process, the latter being very much used of late for illustrating, principally pictorial or portrait work, but there is no process yet to equal first-class wood engraving for mechanical and kindred subjects.

To produce an engraving for this purpose you must either draw or photograph the subject on the wood, the material used being box-wood, cut end way of the grain, and finished to a true and smooth surface. To draw upon this, it must first receive a preparation of either zinc or flake white to facilitate the drawing. When drawn, it is given to the engraver to cut; then from him it is passed to the electrotyper, who takes as many electros as required, and from these the actual printing is done.

When the artist makes a drawing upon the wood, he does not trouble to draw every line by which degrees of shadow are represented in the engraving; he merely shows the light and shade, and leaves the engraver to translate these shades into lines or stipple, according to which would be most effective.

In most of the periodicals of the day we know that many of the engravings have been photographed on the block from the original design or drawing, thus eliminating any chance of error on the part of the artist in making his reversed drawing on the wood. The application of photographing on wood has become so successful in facilitating the work of the engraver that it has come into general use of late, but all photographs on wood are not altogether satisfactory to the engraver, there being ofttimes a film left which sadly interferes with the cutting of fine work.

Photography was applied to wood-engraving purposes by a Mr. Sperge in 1859, and his process was published in the *Photographic News* of December 16 of that year. It consisted of giving the wood a coating of albumen and then of gelatine; when dry, sensitising with a solution of silver nitrate, and the printing operation performed as for paper. It was then fixed in a hot solution of hyposulphite of soda to remove the gelatinous matter, which would otherwise cause great inconvenience to the engraver in cutting.

Coming to the process I am now using, and which I will demonstrate before you this evening, I can state that in no case does it stain the wood, and can make more certain of obtaining a good image than by any other printing-out process.

In the first place the block must be prepared in such a way as to give it a uniform colour, and to fill up the pores of the wood to prevent staining, this being effected by sprinkling a small quantity of zinc white, and adding sufficient albumen, spreading with the ball of the hand until the coating is even and smooth, and finally finishing with a camel-hair's brush. This operation requires some practice to perform successfully. If rightly coated, it will not give any trouble to the engraver, not even with the finest tints. All blocks will not require the same amount of albumen and zinc white, as some are more porous than others. The right proportion can only be obtained by experience. When perfectly dry, sensitise by coating as you would for a collodion plate with the following solution:—

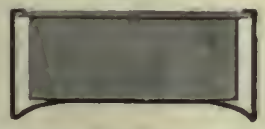
Ether	5 ounces.
Alcohol	5 „
Pyroxyline	20 grains.

When the pyroxyline is dissolved, add seventy-five grains silver nitrate, dissolved in the smallest possible quantity of water. It is best to keep the above in the dark room. This solution gives a slight film, which must be removed from the block before printing. To do this, use cotton wool, saturated with the following solution:—

Ether	5 ounces.
Alcohol	5 „

Dry, and coat again with the sensitising solution before quoted, and apply cotton wool, saturated as before. By giving the block a double coating of collodion, the image prints more rapidly and to a better colour. The block is now absolutely left without any film, and is ready for printing under a reversed negative.

The most simple and quickest method I have found for fixing the negatives and blocks together for printing is by brass clips made for the purpose, such as that shown in the cut. These work very well up to whole-plate size, but for larger blocks I have an apparatus of my own invention, which I shall have the pleasure of showing you.



The time required for printing varies according to the intensity of the light and the density of the negative. With a bright day at this time of the year, with an average negative, one-half to three-quarters of an hour will be found sufficient; with magnesium ribbon, about six or eight feet, burnt at a distance from six to twelve inches away from the negative, will be found ample.

The negative is now removed, and a print is fixed for two or three minutes in a strong solution of hyposulphite of soda, the block then being washed for about half a minute, or even less, when it is placed on its edge to dry, which will take some few minutes. Blocks treated by this process can be produced ready for the engraver under the hour.

W. J. Rawlings.

WHY PHOTOGRAPHS FADE.

III.

The papers made specially for photographic purposes, or for water-colour paintings, by good makers, will be found to stand an exposure to sulphuretted hydrogen for a week without discolouring; how is it, then, that prepared photographic papers, carbon, platinum, and albumenised paper silver prints, will yellow on the surface when put to the same test? That it is not due to the paper is shown by the backs of unmounted prints not changing colour.

As the yellowing must be due to different causes in each process, it will be best to inquire into each case separately. First, as to the carbon process. I have found the surface of the double transfer paper to yellow slightly under the sulphuretted hydrogen test, before any tissue had been transferred to it, which shows that something had been mixed with the gelatine, probably sulphate of baryta and chrome alum, which causes it to discolour; the discolouration of carbon prints, however, is not a very serious matter, because it is but slight, and might be overcome by altering the method of preparing the transfer paper, and is not due to an inherent defect in the process itself. But I am afraid we cannot say the same of either the albumenised paper or the platinum printing processes. I will take the latter first. The yellowing of the whites in platinum prints, when exposed to the same test, must be due to one of three causes.

Either it is due to something used in the sizing of the paper, or the iron is not entirely removed from the paper in the acid baths; or else, as I am inclined to believe is the case, some of the platinum combines with the fibre of the paper, and is not removed. If this is so, it is a very serious matter, especially as printing-out processes are being introduced into the market, which do away with some of the drawbacks to the older process, with its semi-visible image, and no stone ought to be left unturned to make the picture as free from deterioration in the high lights, as it is undoubtedly permanent in the image.

All this beating of the big drum about the permanence of the platinum image by writers in some of our journals seems hardly straightforward, when not one word is said of the yellowing of the paper when exposed to the same tests as those which cause the injury to the silver image, of which they make so much. I yield to none in admiration of the beauties of a good platinum print, but I think all the drawbacks, as well as all the advantages, of any process ought to be stated.

I think it would be as well for the makers of some of the platinum printing-out processes to go into this matter. Only this morning I heard of some prints beginning to go wrong, and they have only been made a few months. If this deterioration is due solely to the platinum combining with the fibre of the paper, there is no doubt a step in the right direction has been made in the cold-bath process, because the platinum is not brought into contact with the paper in the same way as in the other processes.

I now come to the class of photographic papers in which the image is formed of silver, and where gelatine is used as the vehicle instead of albumen. They include the so-called plain salted papers and the various bromide and chloride of silver emulsion papers; and they all, when tested, showed a great advantage over prints done by each of the other processes in what I consider is the most important point, and that is, they did not discolour in the whites of the picture. Perhaps I had better state what my method of testing prints is, because I consider that the only fair way is to expose them to the same conditions, only in a concentrated form, that they would have to undergo by exposure to the atmosphere for a prolonged length of time.

They have to be exposed to a more or less damp atmosphere, containing minute traces of sulphuretted hydrogen gas. Now, dry sulphuretted hydrogen has little effect upon them, and putting them in a solution of sulphuretted hydrogen I do not think a fair test, because the conditions are not the same. I therefore put all the prints I am going to test, comparatively, round the sides of a large bottle, hang a sponge saturated with water from the cork, seal it up, and then pass sulphuretted hydrogen from another bottle through a glass tube passing through the cork.

I have tested prints prepared from probably twenty to thirty different formulæ, and also a large number of prints done on the various emulsion papers in the market. I have seen that they were thoroughly and properly fixed and carefully washed, and every print that I exposed to the above test for more than a week had kept white and unchanged in the high lights, though, of course, the images had been more or less injured.

These tests proved that the whole of the silver had been removed from the high lights of the paper, and that there was nothing in the paper itself that would yellow.

Lately, I was able to examine a number of photographic prints done in 1854 by several of our old noted workers, and none of the plain-paper prints had discoloured in the high lights, so that an absolute test of thirty-eight years was quite in accord with my sulphuretted-hydrogen tests; and, as for the images, almost all of those prints done

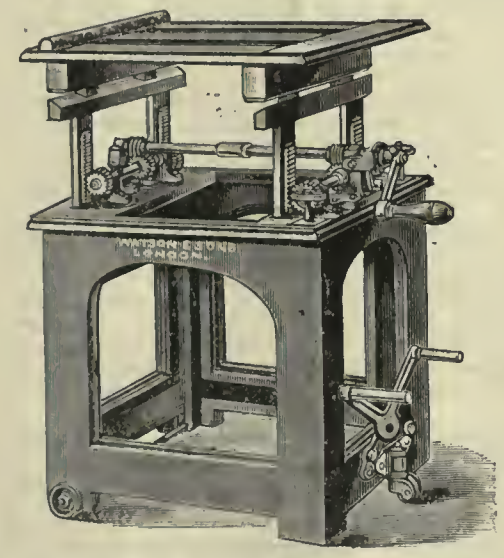
nearly forty years ago had apparently not faded at all, and, as my tests had injured most of the images slightly, we will say that they were equivalent to an exposure of the prints to fair atmospheric conditions for fifty years.

There is no doubt that it was a bad day for the reputation of photographic prints when albumen was introduced as the vehicle, and I am very pleased to see the gradual return to plain-paper silver printing. There is one word of warning necessary, however, in these days of trade competition and wholesale manufacture, and that is, every one who has tried to coat the papers (as received from the manufacturers) with an emulsion knows the vast number of difficulties met with in getting an even surface of emulsion on the paper, &c. To overcome this, various substances have been added to the sizing, &c., to keep the image on the surface and prevent it having a sunk-in appearance. Some of these additions, especially those containing sulphur in any form, will, I am sure, be injurious to the permanence of the prints, and manufacturers ought to be most careful about this matter, both for their own reputation as well as that of their professional customers. HERBERT S. STARNES.

A STUDIO CAMERA STAND OF NOVEL STRUCTURE.

WITH the advent of spring, manufacturers are busily engaged in having novelties for the summer trade made ready for introduction.

One amongst several novelties which were shown us on a visit to the sale-rooms and factories of Messrs. Watson & Son, High Holborn, forms a piece of studio appliance that, we think, will necessarily commend itself not only to the professional photographer, but to all who take portraits, as possessing features of advantage peculiar to itself. This is a camera stand having a square frame, the table surmounting which is capable of being raised or lowered by Archimedean screw-work. This, we are aware, is not new in itself, but where the novelty comes in is found in the fact of *each* of the four elevator pillars being raised and supported by its own rack and pinion, the four racks working with one handle, thus ensuring a high degree



of stability, while, in addition, the front pair and the back pair are capable of being at a moment thrown out of connexion with each other, enabling the hinder pair to be elevated or lowered, while the front remaine fixed, and *vice versâ*. This effects the tilting of even the heaviest camera made, and not only so, but by the action of another piece of mechanism the camera can be raised or lowered while in this oblique relation to the vertical axis, or it can be at once brought to a level position.

By means of a pair of wheels it can be moved in a straight line to and from the sitter, and, by the pressure of the foot upon a lever projecting behind, its motion may be instantly arrested, and the stand rendered as immovable as if screwed to the floor.

Taken all in all, we have not seen a stand which more effectively provides for the rapid and firm adjustment of a large and heavy studio camera. The above cut illustrates our description.

While making this visit we were also shown some cameras specially constructed for photo-micrography, but the pressure on our space forces us to leave over a description.

ELECTRIC LIGHTING IN PHOTOGRAPHY.

[Camera Club Journal.]

WHEN I first had the honour of reading a paper in this room, some eleven years ago, upon my reflector, I was looking forward to the probability, considering the great strides and bounds with which electric lighting was advancing, of being able ere this time to show some important improvement in my invention, if indeed it was not altogether superseded; but, although I have made some changes for the better in details of construction, and with a specially designed lamp secured a steadier light, I must admit that it is practically the same, and I therefore hope you will excuse me if my paper is somewhat in the nature of a *résumé*.

I first turned my attention to the improvement of illumination for portrait photography in 1875, when I patented an improved glass-house, on the principle that every pane of glass visible to the sitter at either end of the studio should face him at an exact right angle, and I effected this by placing the glass in the zigzag crossing of imaginary lines diverging from the sitter's position or chair placed at each end of the studio. My next endeavour, in 1876, was to condense all the actinic light which the dull grey sky of London affords us during the greater part of the year; for which purpose I constructed a plano-convex water lens, using two pieces of plate glass three-quarters of an inch thick, one of which I convexed by heat to the depth of eight inches. The top of this enormous lens, when in its iron frame, reached to the roof of my painting studio; the lens itself, within its iron ring, measured six feet six inches in diameter, and was the largest in the world. When it was first being filled with filtered water (it held 987 pounds) I was standing under it, with my shirt sleeves rolled up, and holding a large sheet of paper in my hand, to watch the increasing brilliancy of a white growing centre sufficiently wide enough to illuminate a head and bust, and surrounded with a dark ring of shadow, when, at the moment of my exultation, there was a terrific explosion, a shower of glass and water, and I found myself on the floor drenched to the skin, and my right fore-arm pierced through between the bones with the point of a huge jagged splinter of glass, cutting the artery, and laying me up for six weeks; fortunately for me, I knew how to improvise a tourniquet. When I recovered and had reconstructed my lens, I realised that it did not go far enough—it was of no use in a good thick pea-soup fog; so I began to experiment with different kinds of artificial light, and having tried the limelight and magnesium light it only confirmed the theory that the relative position of the rays from artificial light is diametrically opposite to that of daylight. In a daylight studio we are flooded with a soft embrace of diffused rays, throwing soft-edged shadows; in artificial light we are struck with the sharp darts of diverging rays from one point, throwing sharp-edged shadows, and even when backing the light with a reflector the direct rays always have the best of it by over-exposing the high light before the reflected rays have time to perform their part. So I saw that it was absolutely necessary to secure such a powerful and steady light that I could afford to do without direct rays altogether, and I constructed a Grove battery of 160 quarts, and secured a Fresnel dioptric light-house lens, four feet in diameter, with a copper silvered reflector of the same size; and using a Serrin lamp, with a platinum screen of four inches to prevent a single ray from escaping, I set to work. I shall never forget my first sitter, a relative of course. He was placed so close to the apparatus that his face turned fiery red, and streamed with perspiration—I literally roasted him. You see I was bound to be on the right side of quantity, considering I cut off all direct rays, and you must also remember those were the days of the slow-collodion process. Of course, the polished silvered reflector was a mistake; it was too much like direct light, and reflected all the heat rays, and so I white-washed it, and from that moment I knew I had solved the problem.

As no London photographer would exploit my invention, and I did not want to lose time, I myself entered the profession in 1877 by starting my present establishment in Regent-street. Fortunately the larger size gas-engines were just then brought out by Crossley, and mine was the first put up in London, much against the advice of Messrs. Siemens, who furnished my first dynamo, and who wrote to me that nothing less than a steam-engine would give a steady light; but an extra heavy fly-wheel overcame the difficulty, and this was the first time that common gas was churned into electric light.

I now constructed a hemispheric reflector, made of zinc, and lined it inside with white enamelled paper, and, as I found my electric arc so large and actinic that I had sufficient light from simple reflection, I abandoned the dioptric lens, with the result of more diffusion, and I have ever since been able to take groups of as many as sixteen people.

At this time I designed the carbon holder, with racket movement, to be worked by hand, which many photographers are now using, but I found in time that this arrangement necessitated too much looking

after, and my present automatic lamp is much more convenient, especially on a drawing-room day.

I tried to replace my single central light of fifty ampères with five or six smaller lamps distributed closer to the surface, but I found, though I might aggregate 100 ampères, I could not obtain the same actinic power; the cause of this is, that in the large lamp the carbons are so far apart that the centre of the positive crater is fully exposed, and the arc is so long as to attain a positive violet colour.

In order to increase its actinic power, I have lately tried to make an improvement in the shape of my reflector by placing around it a zone facing inward, but at such an angle as not to obstruct the light on the sitter. This arrangement throws back and across to the opposite side of the interior of the reflector a portion of the rays of light which were formerly cut off and lost within the small disc; but I find, with the improvement in dry plates, that I really do not need more light; however, it has this advantage, it will help a poor light. This zone should be removable for taking large groups.

Some months ago my studio was connected with the main of the low-tension current of the Pall Mall Electric Light Company, and I sold my old installation after a service of fifteen years. I would here warn any one who contemplates using a supply from street mains for photographic purposes, that the alternating high-tension current is and will be useless until the tearing, roaring noise always accompanying the size of arc that is necessary for good work, say, at least, forty-five ampères, is overcome. I don't think it can be done. I understand several photographers in London have been nearly driven mad with it.

Now, although my light is not as actinic as the brightest sky, still one can take what are erroneously called instantaneous portraits with it. In the group of the Misses Dene I used no head-rest—the exposure was not two seconds, and then, besides the advantage I have of being independent of fog and the night, one can do so much more in the way of obtaining quick changes of effect, and without pulling the sitter about, which would be impossible in a daylight studio. My reflector is suspended with wire ropes running over pullies on a revolving iron frame fastened to the ceiling; and, having a counterweight at the other end, it can be pulled up and down, twisted right and left, and swept round and round by a mere movement of the hand, and, with the aid of a large reflecting screen to illuminate my shadows, photography is a fascinating pleasure, in all weathers, day or night. With the exception of my portraits of the Princess of Wales, which were taken at Marlborough House, every photograph I have ever published or exhibited was taken by my light. I forgot I did place one daylight photograph amongst my exhibits at Pall Mall last year, and I challenged the jury to pick it out.

Some few years ago I built a daylight studio on a new principle for copying large paintings, as I found it impossible to illuminate perfectly evenly large flat surfaces (say, when over three feet square) by one or more artificial lights, for the reason that there is always one corner of the picture nearer to the light in the same room than the other corners, or than the middle.

I have studied, as every photographer must have done, the difference in the effects obtained from light which is reflected from a sunlit mass of clouds and from direct sunlight filtered through gauze or curtains, and I found that this relative difference between cloud-light and sunlight is exactly the same in regard to artificial light. There is a subtlety in the combined crispness and delicacy of the modelling obtained from purely reflected light which no arrangements of gauze or tissues filtering or diffusing direct light can possibly produce; and this proves that in attempting to produce artificial illumination, whether the same be for the painter or the photographer, one should not forget that there is only one kind of light that is worth imitating, and that is the broad and brilliantly white, yet exquisitely soft, reflected light, from a glorious mass of sunlit clouds in the northern sky.

HENRY VAN DER WEYDE.

PHOTOGRAPHY AND PHOTO-MECHANICAL PRINTING.

II.

[Two Lectures delivered before the Officers of the Royal Engineers at the Military School, Chatham.]

ZINC ETCHING.

THE principles of the process of photo-lithography, described to you in the lecture last night, are, by slight variations of working, employed in the processes of photo-zincography and photo-zinc etching, for the production of type blocks. Supposing, now, we take one of the lithographic transfers we have just been dealing with, and, instead of transferring its inked image to stone, we lay it down on a sheet of smooth zinc, the result will be as this, a print on metal which forms the basis of operations for the production of a relief block, *a block on which the lines are raised above the white portions of the picture*, and can be used in the printing press exactly in the same way as a woodcut or type.

Nothing can be simpler than the abstract principles of photo-etching; but, as not uncommonly happens, a considerable amount of skill and experience is required to put these abstract principles into practice.

The theory of etching is, that the surface of a metal, like zinc, is easily dissolved, or etched, by nitric or hydrochloric acid, so long as there is no grease or varnish on the metal to interfere with the dissolving action of the acid. Supposing a piece of clean zinc is coated with wax all over, and it is dipped into acid, no etching will take place, because the wax prevents the acid from touching the metal; but if a drawing is made through the waxed metal with a sharp point, and then the plate is dipped in acid, etching immediately takes place wherever the point has bared the surface of the zinc, and the result would be a sunk or intaglio picture engraved into metal which could be printed from in a copper-plate printing press.

Before we proceed to the etching of such a plate, we ought to tell you how to obtain greasy ink prints or photographs on metal by means other than of the transfer process, and the bitumen process, described to you yesterday. There are several methods, but it will be sufficient for our purpose this evening if we describe one.

The first thing, and the most important thing, is the negative; it must be perfectly sharp, the lines of the subject must be represented by clear glass, and the white paper by dense black deposit, and for the processes we are dealing with the negative must be reversed; that is, the negative image on the glass must be the opposite way round to that on a negative used for printing from direct, the reason being that a reversed picture is required on the metal block, so as to give a *non-reversed* result when the block is finally printed. There are a number of reversed negatives on the table which you may examine after the lecture.

Having obtained a proper negative, the next thing is to print the image on metal. A piece of clean polished sheet zinc, about three thirty-seconds of an inch, is cut to the size required for the negative, and is thinly coated with a solution of gelatine or albumen, water, and bichromate of potash. The plate may be coated with a large camel's-hair brush, or the solution may be flowed over the metal. It is then dried by heat in a non-actinic light, and placed in a printing frame with its sensitised surface in contact with the negative. (Mr. Geddes will prepare before you and endeavour to print such a plate by means of magnesium, and will show you the results of each operation described.)

A few minutes exposure to electric light or sunlight renders the bichromated gelatine insoluble wherever light has obtained access to the plate through the clear parts of the negative, the action being precisely the same as in the case of a transfer. The plate is next covered all over with a thin coating of greasy printing ink, and is then dropped into a flat dish containing cold water. The inky surface of the plate is gently rubbed with a sponge or wool, and the ink coating together with the gelatine leave the plate entirely except where the light has acted through the negative, giving us a similar picture on the metal to that obtained on gelatined transfer paper. At this stage the ink picture on the metal is rolled up with stronger and more ink, and it is then ready for its first etching. As the operations of etching such a plate occupy four to six hours, it is, of course, not possible for us to etch a plate before you, but we have here a series of plates showing the different stages of etching, and as they are handed round to you for examination we will rapidly go over the details of the process. The image on the plate which Mr. Geddes has developed before you first requires rolling up with a stiff greasy ink so as to give the lines sufficient strength to resist a weak solution of nitric acid in water (just strong enough to make the water distinctly acid to the taste) and the plate is kept in this bath for a few minutes, when it is taken out, washed, and again inked, and whilst the ink is fresh finely powdered resin is sprinkled over the face of the plate; the resin adheres to the inked lines, but washes off the bare zinc. The plate is then slightly warmed on a hot plate in order to melt the resin adhering to the lines, so as to form with the ink an acid-proof varnish to protect the lines from being attacked by the stronger acid which is used for the next etching. The acid for this second biting may be about two per cent. solution, and the plate may remain in it for five to ten minutes, the bath containing the acid solution being rocked all the time to prevent air bubbles forming on the surface of the plate, and to ensure even action. After this etching there will be an appreciable amount of what is called "depth" observable, that is, the metal not protected by the inked lines will be dissolved away in a slight degree, and the lines will appear in relief; after this, the operations of inking, brushing with resin, and heating of the plate are repeated, and a third etching is given. The heating of the ink and resin

melts the two together, and has the further purpose of melting it not only on the top of the lines but, as the metal is etched down, the ink flows down the *sides* of the lines as well, preventing the acid *undercutting*, which action, unless stopped, would soon eat out the work from the under side. The inking, melting, and etching is continued in this manner six, seven, or eight times until sufficient depth is obtained to make the lines high enough to ink sharp and clean in a printing press. When the whole of the etching ink is removed the plate is washed, and after one or two finishing or fine etchings it is ready for mounting, when it is trimmed and mounted on a block of mahogany type high ready for the printing press, as those you see before you. Here are finished and mounted blocks with proofs for your inspection after the lecture.

We will now pass on to a further development of this process. Hitherto we have only been dealing with line subjects in black and white. We will now treat with half-tone etching.

HALF-TONE ETCHING.

This important modification or adaptation of the last-mentioned process enables us to produce a type-printing block from hitherto impossible subjects—namely, a photograph from nature, or a drawing in wash. The process has, during the last few years, been so improved upon and developed, that we may safely assert that this method of type-block engraving occupies to-day the first place amongst artistic photo-mechanical processes. Until the principle of breaking up a photograph into minute dots was devised there had been endless futile attempts to convert the gradated tones of an ordinary photograph into a surface printing-block, but the disappointing fact that an inking roller and a printing press absolutely refuse to distinguish anything but lines or dots forced all experimentalists to adopt, in one way or another, the system of dividing up the tone-picture in such a way that it consisted of an agglomeration of dots—dots very close together forming the blacks, dots wide apart the half-tones, and needle point dots the high lights. There are a multitude of ways of attaining this result, and any amount of ingenuity has been brought to bear in rendering the processes as perfect as possible.

Your Sergeant-Major Husband has invented a capital transfer process for breaking up the image on a photograph so as to convert an ordinary photographic negative into a stipple, which can easily be reproduced as a lithographic transfer, or a type-block, by etching a zinc plate on which one of his grained transfers has been printed. We may say that he has not only discovered this useful process, but he has published full particulars, and given it to the world, unlike so many other inventors, who immediately prevent all use of their processes by elaborate patents.

The process, however, for block-making which is most in vogue at the present time is obtained by interposing between the sensitive plate in the camera and the print to be copied a dotted screen or negative which has been obtained by means of photographing an engraved tint of fine-ruled lines. To better explain to you what is meant, we have here a piece of a tint negative, used for this purpose, together with a negative made by interposing a similar tint in front of a sensitive plate in the camera. You will observe, in the half-tone or stippled negative, that the picture is made up of dots, as is likewise this print from the negative on a zinc plate of the image. Here, also, is a finished block, etched on copper by the same process and proof. If you examine the proof carefully, you will observe the dotting we have mentioned. When a similar plate on zinc or copper is etched with acids, the results are like the impression which we show you, and which you will recognise are used now so extensively by so many illustrated magazines, papers, and books. PAUL L. WATERLOW.

(To be continued.) J. D. GEDDES.

THE WET-COLLODION PROCESS.

[Cardiff Photographic Society.]

IN these days of gelatine dry plates it may seem almost useless to devote time and attention to what is now generally considered to be an obsolete process, with all its supposed difficulties and defects; but I hope to show you that it is not the uncertain, troublesome process it is now popularly supposed to be; and I trust I may induce some members of this Society to give it at least a trial, feeling sure they will find it not only extremely interesting, but also capable of producing results unattainable with gelatine plates, whilst the very small cost of materials used in the production of wet-plate negatives should especially recommend it to those amateurs whose means are not equal to their enthusiasm in photographic pursuits.

It is certainly not a process to be commended to that class of amateurs who purchase a Kodak, "press the button," and are content to let the Eastman Company "do the rest." But, to those who delight in doing as much of the work as possible in the art of photographic picture-making, I know of no more interesting instructive process than the now little-used wet collodion, for it allows the amateur, when exhibiting his productions, to exclaim, "I did this myself. It is not an accidental success, but entirely the result of my own skill."

I ask him all seriousness, How much of the credit of a perfect gelatine negative is due to the amateur who exposes and develops the plate? He certainly has the power of selecting his subject, but he has very little control over the character of the resulting negative, except that he may develop it weak, harmonious, or hard, as the case may be; but even in this particular it must to a great extent depend upon guesswork, for it is next to impossible to tell, before a negative is fixed, whether it will be too weak, too dense, or about right.

With the wet-collodion process this uncertainty is entirely done away with, for the film, being so very transparent, enables the operator during development to judge to a nicety what the ultimate density will be when the negative is fixed. Nor is this all, for, in developing a wet-collodion plate, the operator has the power to develop extra detail and density in any particular part of the plate which he thinks may require it, simply by pouring the developer on and off the part in which he desires specially to develop extra detail and density. Further, this power of selection, so to speak, is not confined to development alone, for the same power of modification of the negative is also extended to the process of intensification, either before or after fixing.

Another advantage of the wet-collodion process is, that the result is known to a certainty within a few minutes after exposure, and, as the development is carried out on the spot where and when the negative is taken, the subject is so strongly impressed upon the mind of the operator during the development of the plate, that he has a clear conception of the requirements of the case. This, with the power of modification during development and intensification, enables the operator to impress his own ideality upon the negative. With the gelatine plate this is all changed.

In the first place the plate has to be purchased ready-made, and has to be taken in all the glorious uncertainty as to whether it is good, bad, or indifferent; quick-acting or slow.

Thus, when taking some important subject which it may be impossible to take again in case of failure, the poor operator is likely to get into a frame of mind greatly to be pitied. Add to this that the plate is not developed till possibly weeks or months afterwards, when the operator can have no clear conception of the subject the plate was exposed upon, and also the inability to judge the character of the developed image till it is fixed, leaves the quality of the resulting negative almost as much to luck as to judgment.

It may be said against the wet-collodion process that, as the plate has to be prepared, and also developed within a few minutes of exposure, it necessitates the carrying of baths, chemicals, and tent into the field. But this is not the formidable undertaking it may at first sight appear, whilst it allows of an almost unlimited number of good negatives being obtained with certainty.

The dry plate, even in the field, does not contrast so favourably with the wet plate as regards weight to be carried as may appear at first sight; for, if a number of negatives have to be taken on dry plates, it necessitates the carrying of a number of dark slides, which, with their plates, are both bulky and heavy; besides, the constant danger of light gaining admittance to the plates, either by accident or the carelessness of would-be friends, tends to keep the poor operator in a continued state of anxiety.

With the modern forms of light cameras and stands, a wet-plate outfit for field work need not be much more weighty than for dry plates. A small bottle of collodion, a water-tight ebonite bath filled with sufficient solution to cover the plate, a few ounces developer and a similar quantity of u weak acid, gelatine solution (of which I will speak further on), together with a number of clean glass plates, are all that is required, except the developing tent, which need be neither heavy nor bulky, and may take the form of a light box to carry cameras, chemicals, &c.

The cost of chemicals consumed in the production of wet-plate negatives is so very small as to be considered almost *nil*, so that the difference in the cost of a couple of dozen whole-plate negatives by the wet-plate process would pay for the luxury of a light porter to carry the wet-plate kit into the field, thus reducing the labours of the amateur to less than they would be if he carried his own camera, double slides, and dry plates.

A great deal of misconception exists, and always has existed, as to the *supposed difficulties* to be met with in the practice of the wet-collodion process. If you turn to the photographic publications of some twenty years ago, you will not fail to observe that the great topic dwelt upon was the "Negative Bath," with the host of troubles it was supposed to be afflicted with, which would lead one to suppose

that it was almost, if not quite, impossible to keep the negative bath in decent order. But, in point of fact, nothing could well be simpler, provided common sense be used, instead of the fussy, meddlesome quackery to which the poor, ill-treated negative bath was almost universally subjected. I can only compare the insane treatment to which the negative bath was subjected to the manner in which great numbers of persons treat their liver, taking first a course of Purgeham's pills, followed by another of Astringham tonic bitters; then applying one of Stickham's plasters, and Shockham's electric belts; and, finally, thinking they feel awfully bad, and that, unless they keep up this treatment for ever and ever, they will never get well again. Now, if such misguided folks would only leave their liver alone, or treat it with common sense, they would not only live the longer, but would scarcely be aware that they possessed such an organ as the liver.

So with the negative bath; treat it with common sense, and do not mess it about, and you will experience but very little trouble in keeping it in perfect order.

It is scarcely necessary that I should trouble you with formulæ for bath developer, &c., as Mawson & Swan have just published a third handbook upon the process, which treats the subject in all its details; but I would like to refer to the acid gelatine solution I have previously mentioned, and which I have found extremely useful when working the wet process in the field, as it saves the necessity of carrying either fixing solution or washing water.

The solution is prepared somewhat as follows:—

Dissolve about a drachm of gelatine or glue in about an ounce of glacial acetic acid, then add about a pint of water and an ounce of methylated spirit. (If the acid be not at hand, four or five ounces of strong vinegar may be substituted for it.)

As soon as a plate is developed, drain off the developer and apply a small quantity of the acid gelatine solution, which runs all over the plate, pour off and repeat with another small quantity, which pours off as before, and put the negative into a grooved plate box, to be fixed at some future time, after being well washed. The proportions of this acid gelatine solution may be greatly varied without impairing its results.

To an old photographer like myself the sight of a good collodion negative, with its fine texture, clear shadows, free from the slightest trace of colour, does one's heart good, and makes us sigh for the "good old days" when personal skill, rather than good luck, produced the finest results.

For the production of transparencies for the lantern no process can equal wet collodion, for it not only gives perfect clearness in the lights, but also a peculiar transparency in the shadows which no other process can produce.

In comparing a collodion transparency with one produced on a gelatine plate, they should be placed in the lantern, for it is only by these means that the superior excellence of the collodion transparency can be fully realised.

Compared side by side *out of the lantern*, the gelatine transparency may appear the better of the two; but, when exhibited *in the lantern*, the superior excellence of the collodion slide is at once apparent.

Very excellent slides may be produced with the same collodion, bath, and developer as is used for negatives; but, if the highest results are desired, an older collodion, a more acid bath, and a well-restrained developer should be used. The only drawback to the process is that it cannot be used for making transparencies by contact, it being impossible to place the plate in close contact with a negative without injury.

If it should appear to any member of this Society that I have too strongly advocated the claims of the wet-collodion process, I must crave as my excuse that I have been pleading the cause of my first love, who taught me to "hold the mirror up to nature," and to fix her image thereon.

I will now proceed to give a practical demonstration of the process, first making a negative from a transparency, that you may see how favourably the development of a wet plate contrasts with that of the gelatine dry plate, both as regards the time occupied and facility for modifying the character of the negative. I will then proceed to make a transparency from a negative, showing the adaptability of the process for the production of transparencies for the lantern.

The coating of the plate with collodion, you will observe, is almost identical with the varnishing of a negative, except that it can be done more leisurely. After pouring off the collodion into the bottle and replacing the stopper, proceed to pinch the lower edge of the plate between the finger and thumb, and as soon as the collodion has set sufficiently to retain a definite impression of the thumb, it is ready to be immersed in the silver bath by means of the dipper. This must be done with one slow, steady movement, for, if it be done by jerks or stoppings, lines across the plate will be the result.

After the plate has remained in the bath about three minutes, it may be raised, and if the solution runs off without signs of greasiness it is sufficiently sensitised, and, after well draining, it may be placed in the dark slide ready for exposure.

The exposure in daylight should be about ten times longer than would be required for a gelatine plate of average speed, but as I shall carry out this experimental exposure by the light of a candle, and as the exposure will be five or six minutes' duration; I will utilise the time by describing what I term the "common-sense" treatment of the negative bath.

Now, it is a well-known fact that a *pure* solution of silver nitrate, when exposed to the light, remains clear and colourless, but, if the solution contain any organic impurities, it will (unless it be acid), first become discoloured, and finally become clear and bright, with a black deposit at the bottom of the bottle. Bearing this fact in mind, if a bath gets out of order through impurities being introduced, all you have to do is, first free it from acid by the addition of a solution of sodium bicarbonate, expose to light till clear, when you will have a pure solution of silver nitrate, which only requires the addition of a few drops of nitric acid, and you have a bath in perfect working order.

But it should be borne in mind that the solution must be filtered *before* the acid is added, else the addition of the acid would enable the solution to take up a portion of the organic impurities by dissolving some of the deposit in the bottom of the bottle; hence the necessity of filtering the solution *before* the addition of acid.

I will now proceed to develop a negative on the plate I have exposed behind a transparency to the light of a candle.

You will see I do not require a dish to develop the plate in, as it is held at one corner by the finger and thumb, and, instead of using an ounce or more developing solution for a quarter-plate, I place in a measure about a drachm of solution, and unless my hand has lost its cunning through want of practice of the process for many years, I shall only use about half a drachm of solution to develop the plate, as I wish to develop this plate to full density so as to save the trouble of intensification. To those who have never seen a wet plate developed it will seem surprising to see the rapidity with which the development proceeds, the process being complete in about thirty seconds; but, as the film is so transparent, there is no difficulty in judging when the plate is sufficiently developed, without the uncertainty one feels when developing the opaque gelatine film.

The development being completed, I wash the surface of the plate with a small quantity of water till greasiness disappears, then fix by pouring the cyanide fixing solution on and off a few times, wash with a few ounces of water and dry the plate over the gas flame, the whole process occupying but a few minutes from beginning to end.

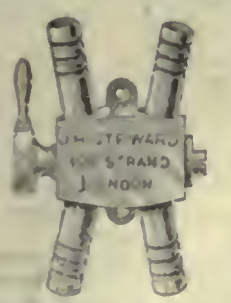
My object in bringing this subject before you has not been merely to entertain you, but to prove to the present generation of amateur photographers that the wet-collodion process is not so uncertain or difficult as it is popularly supposed to be, and thus to induce some of the members of this society at least to take up one of the most interesting and instructive processes connected with the practice of photography.

THOS. FORREST.

Our Editorial Table.

A Cut-off Tap for the Oxyhydrogen Light.

MR. J. H. STEWARD, 406 Strand, has introduced a cut-off tap for the lantern, which, in our estimation, will prove very handy. The advan-



tages claimed are that the operator, having once adjusted his apparatus

and his light, may turn it down and leave it in the certainty, that on returning he has only to turn up the lever handle to get the same light as before. There is a bye-pass in the hydrogen plug by which the gas is not allowed to go out at any time. The whole thing is simple, and is adaptable to any single or dissolving-view lantern, and must prove valuable in enlarging or micrographic work.

The "Nys" Dry Plates.

Mr. Robert C. Murray, 8 Garrick-street, Covent-garden, W.C., the agent for these plates, has submitted samples for trial and criticism. We have found them very sensitive, so much so as to receive a well-impressed image with a momentary exposure of a lens severely stopped down. The image develops up both bright and clearly, with all the requisite gradation and intensity.

PATENTS COMPLETED.

An Improved Photographic Magazine Camera and Appliances used therewith.

No. 8055. Herbert James Tear, 12, Clapham-road, Stockwell, Surrey, and Arthur Lewis Adams, 81, Aldersgate-street, City of London.—*March* 5, 1892.

This invention relates to an improved photographic magazine camera and appliances used therewith, and our said invention is designed to produce an economical, simple, and effective form of magazine camera, by means of which dry plates or other sensitive surfaces used in photography may be stored for use, and each successively brought into the position in which it is required to be held during exposure, afterwards being removed into a separate receptacle, allowing a fresh or other sensitive surface to be brought into position, all these changing operations and the storing receptacles or reservoirs being entirely within the camera case.

We construct the camera advantageously of an oblong rectangular form, in the front end of which is placed the lens, and in connexion therewith we use any suitable shutter—for instance, a weighted shutter, moving upon an axis and operated upon by levers or suitable attachments.

The end of the case or camera is divided into two parts, horizontally. The upper compartment forms a receptacle for the sensitive plates or surfaces previous to exposure. The upper compartment contains a movable part or sliding partition placed behind the plates, and acted upon by a spring, or springs, which is regulated by means of a cord or other convenient attachment passing through the camera case—advantageously out at the back. The plates are held in position by the spring pressing the said sliding part and forcing them against projections in the body of the camera. The front plate, having no platform or support under its bottom edge on the pressure of the spring being released, such front or foremost plate falls upon a hinged plate or shelf, which is capable of being raised by means of a lever beneath it being acted upon by means of a cord or other suitable attachment, and the sensitive plate then slides into a lower compartment or storing reservoir.

Glazed non-actinic paper, or other convenient material, or a sheath, is applied to the back of each sensitive (or transparent) surface, or same may be mounted or protected in any suitable manner.

When flexible films are used, a rigid substance advantageously glazed is prepared on one side with a suitable adhesive material.

An Improved Photographic Print Washer.

No. 22,758.—George Frederick Firth, Oakleigh House, Stanley, near Wakefield, Yorkshire.—*March* 5, 1892.

The apparatus consists of two metallic tanks, placed one above the other, and in each is fixed a syphon. The prints are placed in loose trays, in a frame, and then put into the lower tank. Water is then poured into the upper tank, and discharged by means of the syphons. The prints are alternately soaked and drained, thus effectually washing the prints.

LONDON AND PROVINCIAL PHOTOGRAPHIC ASSOCIATION.

March 31,—Mr. E. Clifton in the chair.

Mr. R. G. F. Kitson was elected a member of the Association.

Mr. W. J. Rawlings read a paper on *Photography on Wood* (see p. 230), and at its conclusion he exhibited a frame of his own contrivance for printing from the negative on to the sensitised wood block. This consisted of a sheet of glass resting on a rebated frame cushioned with indiarubber. Blocks of different sizes could be held in contact with the negative by means of a frame having various screw adjustments. In answer to questions, he said he found ordinary sheet glass flat enough for the purpose. There was no chloride in the sensitising solution.

The Chairman said that carbonate of silver was probably produced by the reaction of the zinc white on the nitrate of silver.

Having exhibited several engravings on wood cut from photographs, also photographs ready for cutting, samples of blocks—including one which could be worked on by four engravers at once—Mr. Rawlings proceeded to demonstrate his process, first of all coating a block with zinc white and one or two drops of egg albumen. This he rubbed in with the ball of the hand, remarking that it needed a great deal of practice, and should be worked from side to side or end to end. Having sensitised the block, he dried it over a spirit lamp, dissolved off the film with ether and alcohol, sensitised a second time, and again removed the film. He preferred magnesium to daylight for the exposure, alleging that he got a better depth of picture, using six and a half feet of magnesium at a distance of three to four inches for the negative he had with him. He thought six inches about the best distance, as if too close to the block the heat sometimes curved it. He showed some reversed negatives obtained by exposing through the glass, which were perfectly sharp. He fixed in a solution of hypo six ounces to twenty, and washed for about fifteen seconds by projecting a stream of water on to the surface of the block. He dried the negatives by removing moisture with the hand and applying heat in preference to alcohol. The photograph on wood could thus be produced under the hour.

Mr. A. L. HENDERSON asked the object of the second sensitising, and what was the difference between Mr. Rawlings' process and Crookes's? He (Mr. Henderson) had practised photography on wood for some years, and did not put any preliminary coating on the block, and yet the details were perfectly visible, and it could be cut very nicely. He also alluded to the collodion transfer process for the purpose, the film being transferred to the wood in alcohol, silver next to the wood.

Mr. RAWLINGS said he had tried Crookes's process and found it much too slow for practical purposes.

Mr. DAWSON said that in photography on wood subsequent alterations were sometimes found necessary. He asked for the experiences of those present on the point.

Mr. RAWLINGS said that by Mr. Henderson's process pencilling became difficult.

The CHAIRMAN said the surfaces of Mr. Rawlings' blocks could be pencilled freely; and Mr. CLARKE said they were the finest possible surfaces for pencilling.

Mr. DAWSON (continuing) said the subject brought before them by Mr. Rawlings that evening was of enormous interest. By his process, not only was expense saved, but valuable originals were preserved. Millais and other artists used to draw direct on the wood, and thus engravers would cut away most valuable copyrights. Mr. Rawlings' process was better than anything he (Mr. Dawson) had to do with personally. He had attended half a dozen lectures at South Kensington, and the information he had obtained was compressed within half a minute, and disappointed him. Mr. Rawlings had shown them that his process was practicable in the studio, and also for rough-and-ready purposes.

Mr. J. TRAILL TAYLOR said Mr. Rawlings' process was analogous to one formerly published by him in the *Photographic Times* of New York. This consisted, if he recollected aright, in coating the block with collodion containing nitrate of silver and nitrate of uranium. The latter reduced the silver nitrate. He had produced good results by the method, and to the satisfaction of a friend who was an engraver for *Harper's Magazine*. He (Mr. Taylor) afterwards began to think as to the utility of the collodion at all, and tried to simplify it to this extent. He took a little carbonate of lime in the form known as Spanish whiting, mixed some silver nitrate with it, and applied it to the wood. It gave a most sensitive surface and a brilliant image. He fixed by simple immersion in water. He did not carry it to any practical extent, but could recommend it very strongly.

Answering Mr. Henderson's question as to the object of the second sensitising, Mr. RAWLINGS said it gave double the rapidity. He had tried double the amount of silver in one coating, but two coatings with half the strength of silver gave a much better image.

Mr. CLIFT exhibited a wood block having a collodion transfer upon it; he said it could be pencilled upon, and the film need not interfere with the cutting.

Mr. H. W. BENNETT said that Mr. Rawlings' process was one of the most valuable he had seen. The objection to the collodion transfer process was that the collodion frequently peeled in very fine work, and it was impossible to see the fine shading in the detail. He had also found it difficult to pencil on. In Mr. Rawlings' process it was an improvement that they were able to pencil on the blocks, that it gave a white basis, and no film to speak of. He repeated that it was one of the most valuable processes he had seen.

In reply to a question,

Mr. RAWLINGS said he had not patented the process, and that anybody was welcome to work it.

Mr. HENDERSON suggested celluloid, with bone dust as a basis, as a substitute for the wood.

After some further discussion,

The CHAIRMAN moved a vote of thanks to Mr. Rawlings for his paper and demonstration, as well as for making the process free. He (the Chairman) had tried every process published. He had not succeeded with the transfer process, but did with a negative process, applying printer's ink to the block, sensitising with collodion emulsion, and taking a picture direct on to it. He got a fair negative, developing and fixing in the ordinary way. It was something like a ferrotype on the block.

A picture taken by Mr. Wellington with Dallmeyer's new teleo-objective was shown; also one taken from the same point with an ordinary lens.

Mr. Henderson exhibited some ink photographs by Mr. G. Pendry, of Nottingham, which that gentleman presented to the Association. Mr. Pendry having been thanked for the gift, the meeting closed.

Holborn Camera Club.—April 1, Fourth Annual General Meeting, Mr. T. O. Dear (Vice-president) in the chair.—The SECRETARY read the report of the Committee for the past year, in which they congratulated the members of the Club on the very successful year which had just ended. The social events had been excellently attended, while the lectures and demonstrations by various gentlemen had proved excellent. During the summer (!) months the outings proved very successful. The following places were visited: Waterlow Park, Pinner, Purfleet, Radlett, Broxbourne, Keston, and Hyde Park. The garden party in July was a notable success, and the week's sojourn to the Southern Counties' Cyclists' Camp at Dorking this year compared favourably with the past. The lantern shows had been numerous, and the report concluded with an expression of the regret of the Committee at the loss which the Club has sustained in the retirement of Mr. Smith, the late Hon. Secretary. The TREASURER read a statement of the income and expenditure of the Club for the year ending March 31, 1892, showing a nett balance of £15 16s. 2d. The reports having been adopted, various alterations in the rules were proceeded with. The subscription was raised to ten shillings and the entrance fee abolished. The Officers and Committee were then elected:—*President:* Mr. A. Horsley Hinton. *Vice-Presidents:* Messrs. Fred Brocas, S. T. Chang, E. Clifton, T. O. Dear, D. R. Lowe. *Committee:* Messrs. E. H. Bayston, A. T. Elsworth, A. J. Golding, A. Hodges, F. Knights, J. Stevens, H. West. *Hon. Treasurer:* Mr. Albert Bell. *Librarian:* Mr. J. Brittain. *Hon. Secretary:* Mr. F. J. Cobb. *Assistant Hon. Secretary:* Mr. Herbert Thompson. Ten members, on Saturday last, visited the Victoria Docks, and went on board *H.M.S. Grafton*, a new war-vessel which is being built in the docks. The Abbey Mills Main Drainage Works were also visited.

Polytechnic Photographic Society.—March 29, Mr. Quintin Hogg in the chair.—CAPTAIN GLADSTONE delivered a lecture on *Westminster Abbey* before an audience of about a thousand members and friends. The lecture was historical and architectural, and was illustrated by upwards of fifty lantern slides made by the lecturer from his own 12×10 negatives, the exposures for which had varied from two seconds to two days. The author conducted his audience round the Abbey, explaining the various historical and other events connected with each chapel and tomb in turn as the picture was thrown on the screen. The slides were remarkable for their detail, vigour, and softness, and full justice was done to such beautiful portions of the Abbey as Henry VIIth's Chapel and some of the Royal tombs.

Croydon Microscopical and Natural History Club (Photographic Section).—April 1, Mr. J. A. Carter, R.A., in the chair.—Mr. Baldock exhibited one of Chadwick's stereoscopes. Mr. A. J. E. HILL then demonstrated the *Cresco-Fylma Process for the Enlargement of Negatives and Transparencies without the Aid of Optical Appliances.* Ferrous oxalate and hydroquinone developed plates were recommended in preference to pyro-ammonia as being more easily manipulated. Some fine specimens in all stages of enlargement, from quarter-plate upwards, were exhibited, and apparently being free from distortion and loss of density whatever. The CHAIRMAN said that what he had seen that evening fulfilled everything that Mr. Hill had claimed for his process.

Bath Photographic Society.—March 30, Mr. Austin J. King (President) in the chair—The Chairman introduced the lecturer of the evening, Mr. E. J. Appleby, who read a paper on *Stereoscopic Photography*, and supplemented his remarks with a demonstration of printing transparent stereographs. Mr. APPLEBY pointed out that many were under the impression that the stereoscope was a recent development of the art, but in the fourth and fifth decade of the present century it was practised more than any other system; but so much had the work relapsed that hardly any mention was made of it in standard works published within recent times. The lecturer then described the conditions necessary to produce a picture which should appear solid when viewed in a good instrument (not necessarily an expensive one). He also spoke of the power which can be acquired by training the eye to see pictures of solid objects solid as in nature. By means of numerous examples the lecturer illustrated the necessity of correctly estimating the parallactic angle; thus, the moon would represent many thousands of miles, near objects the contrary. Defects in manipulation were pointed out, as well as faults distinctly traceable to imperfect stereoscopes. Messrs. Rose & Co., London, sent two new hand cameras for exhibition at the meeting. They were really double cameras, one used for securing the object on the sensitive film, the other portion intended as an exact guide to the work the instrument was performing. These were examined with great interest, and led to a discussion on detective camera work generally.

Bristol Camera Society.—April 1.—The subject of intensification of negatives drew a number of interested members, who thoroughly discussed the various methods of intensification by mercury, uranium, silver, redevelopment, &c. The discussion led to the admission that each process was the best under suitable circumstances, while for general use, when only one intensifier was desirable, mercury and ammonia is to be preferred.

Leith Amateur Photographic Association.—March 29, Mr. W. M. Smith (Vice-president occupied) the chair.—Mr. Alexander Pitkethly brought before the members the results of a somewhat exhaustive series of experiments he had been making with several of the newer developing agents. With para-amidophenol on gelatine plates of moderate rapidity, and with a good and sufficient exposure, he had found it to act in a very energetic way, giving a negative very clear, free from stains or yellowing, which although thin was full of detail in the most shadowed portions. Samples were passed round, and his judgment generally verified. He also showed a number of bromide prints and lantern slides, which were much admired, the developer being rodinal, which, for this class of work, clearly showed its advantages and disadvantages.

Liverpool Amateur Photographic Association.—March 31, the President (Mr. W. Tomkinson) in the chair.—Three new members were elected. Mr. E. M. Tunstall introduced the subject of *The Lantern Mission: What it is, and what it may become.* In a few words the speaker referred to the history of the movement, which was already supported by some of the best photographic workers, and pointed out the advantages that were to be derived by members of such an organization, as well as the beneficial work which they might do for others at the same time. The next subject was the discussion of two alternative schemes for new club-rooms. A copy of the plans was in the hands of each member (having been prepared free of cost by two of the members), and after full discussion it was unanimously decided to adopt the

scheme recommended by the Council, provided the premises could be obtained on satisfactory terms. Mr. Fred Anyon then gave a lecture on *Art in Relation to Photography*, illustrated by lantern slides. The lecturer first emphasised the distinction between taking a photograph and making a picture, pointing out the general rules of composition, and showing how far they might be applied to photography, and then proceeded to illustrate his meaning by throwing upon the screen photographs of the same scene taken from an artistic and an inartistic point of view. Many of the pictures were Mr. Anyon's own work, and proved him to be well qualified to give advice upon the subject he had in hand. The lecture was listened to with close attention by a large audience.

Midland Camera Club.—April 1, Dr. Hall Edwards in the chair.—Mr. Walter D. Welford gave a paper upon *Hand Cameras: their Construction and Use*. Dealing first with the want of success so often heard of, he explained that a hand camera required more experience and practice than an ordinary stand camera. Next followed an attack upon the word "detective," and the abuse of indiscriminate shooting off. Lenses and shutters being disposed of, the various cameras in the market were dealt with in the following order: Box cameras, bag changers, well system, groove reservoir, lever movements, and reflector principles. The following were amongst those shown: Griffiths' Two Guinea, Ashford's, the Talmer, the Cytox, the Alert, the Ideal, Crouch's, the Artist Twin Lens, and the "Itakit." The latter, which is of metal, very simple in construction, and carrying twenty-four plates, was shown by Mr. W. J. Spurrier. Mr. Welford next dealt with the position in which to hold the camera, and urged every user to thoroughly study the mechanism at home first. He concluded with advice as to street scenes, and a strong appeal to members to utilise all opportunities in that direction. In addition to the cameras, a series of negatives taken last week were shown, and at the end of the paper some 200 slides were exhibited.

South Manchester Photographic Society.—The first meeting of the newly formed South Manchester Photographic and Lantern Society was held on Monday, at the Longford Lecture Hall, Stretford. Mr. W. I. Chadwick, the Chairman, stated the object and scope of the Society. There were other societies in Manchester, and it was not intended to compete with any of these. There were a considerable number of amateurs living on the south side of the city who preferred a meeting place nearer home, and it was not intended to extend the membership to an unlimited extent, as smaller societies have oftener proved to meet the object more efficiently. Another great inducement in favour of Stretford was the magnificent accommodation afforded by the rooms, with conveniences such as few photographic societies in the world can boast of. They have been generously placed at the disposal of the Society by Mrs. Rylands. The meetings will take place monthly, with technical or instruction meetings and popular or exhibition meetings alternately, and to the latter members may invite friends. There will be outdoor meetings during the summer months. The management of the affairs of the Society is vested in the hands of the officers and members present at the monthly meetings. Thus every member has an equal voice and vote as regards the interests of the Society. A library has been started, and an enlarging apparatus of the most perfect kind has been presented to the Society for the use of members at their own homes; and, if the support is accorded to the Society which is hoped for, there are other possibilities in the near future. The annual subscription has been fixed at ten shillings, but for members joining after the February meeting the subscription will be five shillings for the first half-year. The Hon. Secretary, Mr. M. W. Thompstone, Beaufort House, Brocklands, will supply any further information to inquirers. Mr. Chadwick afterwards showed a large number of photographs made from negatives taken by himself during the past year. He took the members through some of the finest scenery that we have in England, including scenes in the Isle of Man, Isle of Wight, Windsor Castle, Dovedale, Chatsworth, Hadden Hall, Cheshire, concluding with some very beautiful views of the Museum at Peel Park.

Correspondence.

☞ *Correspondents should never write on both sides of the paper.*

"PHOTOGRAPHIC PORTRAITS."

To the EDITOR.

SIR,—Not long ago a wordy warfare raged in the photographic press between the admirers of the older system of pictorial photography and a small number of others whose leanings were towards a style which differed in character in some respects. Possibly at times the disputants became rather heated, but, on the whole, there was little which could be called absolutely objectionable.

Recently I have noticed in your columns some communications on the subject of the rival systems, which, although, in my opinion, based on erroneous ideas, and sometimes perhaps rather humorous than serious, call at present for no direct comment. A paper, however, called the *Optician*, has lately reached the Camera Club, and an article therein has been pointed out to me which, I think, should not pass altogether unnoticed. The article is entitled "Photographic Portraits," or some such title, if I remember rightly. I do not propose to enter into any discussion concerning the misrepresentations which it contains relating to a phase of photography which some of us take pleasure in practising. It is rather to the tone of the article that I wish to refer, in the hope that some restraint may be placed on a system of comment which is not infrequent, though rarely of such an unsavoury character as in the present instance.

It is difficult to believe that the editor of the journal in question can have been aware of the nature of the paper which he has allowed to appear in his columns, for it is inconceivable that any respectable journal should consent to publish such gross and vulgar personalities. The references to Mr. George Davison and Mr. Gambier Bolton (there is no necessity to mince matters or affect ignorance), are in as bad taste, to say the least of it, as they are uncalled for. Happily, both these gentlemen can well afford to treat them with the contempt which they deserve, and I need not further refer to a subject which becomes the more unpalatable the more it is considered, except to express a hope that this, being entitled No. 1 of a series, the editor of the *Optician* will have the good feeling to allow it to be the last.

But on the general question of the attacks made on those who practise a system of pictorial photography which happens to have some original features, may I ask, Why this virulence, why this intemperate denunciation? Do our exhibitions or galleries teem with this class of work? Is there danger that it should oust all earlier and more popular methods? How many are there who practise it? Sir, I challenge the writers of the articles to which I refer to name ten; in fact, I challenge them to name five photographers who adopt this system. If there are more, I should be happy to know it; but, if so few, why is it necessary so frequently to unmask this battery of delicate sarcasm, to bring to bear such ponderous artillery against, at most, half a dozen men who endeavour to please themselves and others in a somewhat unconventional manner? Can they not be left alone? Is their influence so much to be dreaded? So much attention, surely, might have a smack of flattery about it, if flattery of the kind could be acceptable to those to whom it is addressed.

It is not uninstructive to note that the opposition to the class of work to which I allude comes almost solely from photographers. The general public does not appear to be by any means so antagonistic. Now, from the point of view of scientific photography, I do not blame these objectors. But why, again, this virulence? I have, I am happy to say, more than one friend who is wholly scientific in photography, and they tell me candidly that they do not like, for instance, my own pictures. Well, we agree to differ, and we do not necessarily retort upon each other with coarse and strong language. So, with regard to these photographers, if their method is worthless, why not let it meet the certain death to which, on this account, it would necessarily be destined? If, on the other hand, it has value in it, surely its advocates might be allowed to give pleasure to those who could derive pleasure from it.—I am, yours, &c.,

London, April 5, 1892. ALFRED MASKELL.

STEREOSCOPIC PHOTOGRAPHY.

To the EDITOR.

SIR,—Upon looking over my article in last week's copy of this JOURNAL, I can imagine a misunderstanding might arise from the last paragraph, and some further remarks are necessary.

Near the centre of the retina of the human eye is a "yellow spot." When the image of a distinct object falls upon the centre of this yellow spot, a distinct impression is formed in the brain, and we see distinctly; but, when an image falls upon other parts of the retina, it is conveyed to the brain in a less distinct manner, that is to say, all other parts of the retina radiating from the "yellow spot" are less sensitive, and the mind receives images from these parts in what a photographer would call out of focus. When we want to see an object, we turn our eyes in the direction of that object, and thus bring the image formed by the crystalline lens into the centre of the yellow spot, for, as has already been said, this is the only place where distinct vision is possible. It is therefore manifest that we can only see a point of an object distinctly at a time, and all other parts of the object are indistinct, or out of focus; but, by experience from very early infancy, we associate these indistinct images in a certain way, and we know what they mean. For instance, when we have learned to read by a momentary glance at a word of eight or ten letters, we know what these letters mean. If we look at the initial letter in the word "stereoscopic" first with one eye, we concentrate our attention for the time on the letter "s," and we see it, or part of it, distinctly, and the other letters will be more or less indistinct, though by practice in reading we know instantly what they mean. If, now, we look at the letter "s" with *two* eyes, each retina will receive a similar image in a similar way, and by experience the two images are combined in the brain, and we know we have only one object before us, but depending upon the distance the object be from the observer, the indistinct images (alike in both eyes) will fall upon different parts of the retina which are more or less sensitive, and by experience again we know we are looking at a flat object.

But, when we look at an object of three dimensions with two eyes (the object may be something near at hand, or it may be a landscape) we converge the optic axis to some particular point so as to bring it upon the centre of the "yellow spot" of the retina. Now, it will be seen that all other objects around the particular point are not only indistinct, but they are *not alike*, in each retina, for with one eye we see more of one side of the solid object than is visible to the other eye, and these indistinct

images which are not alike do not correspond in the same way; they would if the object was flat, and by experience and association with other mental faculties we know them to be solid. When we look at a near object, the convergence of the optic axis is greater than when a more distant object is observed, and the dissimilarity of the indistinct images is more pronounced.—I am, yours, &c., W. I. CHADWICK.

Manchester, April 6, 1892.

RATIO OF GRADATION.

To the EDITOR.

SIR,—In your issue of the 25th inst., "Free Lance" asks me a question which I have already answered in the previous number of the JOURNAL. I will, however, answer it once more. The experiments of Messrs. Hurter & Driffield show that the gradations of a negative are "almost identically the same whatever developer be employed." But "there is a theoretical possibility that a plate may be rapid to one developer and slow to another."

It is therefore true that beyond a trifling limit the photographer has (according to Messrs. Hurter & Driffield) no means at his disposal for altering the gradation; but we cannot say that he never will have such means at his disposal. The difference with eikonogen is altogether inconspicuous and of no avail for practical purposes, as far as the recorded experiments go. The diagram No. 14 clearly proves this.

Now, "Free Lance" says the gradation can be changed at will. Beyond this insignificant difference? If so, let him do it; if not, why juggle with the question? There is nothing whatever absurd in my challenge; we have had quite enough of people who, in their easy-chairs languidly beg to differ from Messrs. Hurter & Driffield, find all manner of faults with their instruments and their conclusions, and, having said everything (but done nothing) to damn their work, end by expressing the greatest admiration for these able investigators. I imagine that Messrs. Hurter & Driffield care little for such praise, and that my simple statement "they have laid the foundation for a quantitative science of photography," will sound sweeter in their ears than all that has yet been said or written about them.

"Free Lance" seems in doubt whether I was guilty of rudeness to him, or of throwing "surreptitious mud" (whatever that may be composed of) at Messrs. Hurter & Driffield. I told him he was unnecessarily discourteous to them; when he cries *peccavi* I shall be happy to stand him coffee and cigars. Mr. Bolton's experiments are highly interesting; I shall try to learn more about them and their significance.—I am, yours, &c., R. C. PHILLIPS.

Arts Club, Manchester, March 28, 1892.

FOCUSSING EYEPIECES.

To the EDITOR.

SIR,—Your article in this week's JOURNAL upon "the use of focussing eyepieces," brings before photographers such a time-saving system of focussing, that I am sure none who have tried it will ever give it up.

With your permission I will explain a little dodge in connexion with the use of eyepieces, that very much increases the delicacy of the image formed.

Having carefully adjusted and fixed the focus of the Ramsden or other eyepiece, procure five circular glass microscopic slide covers (½ inch is a convenient size), and cement them with Canada balsam on to the ground side of the camera screen, one in the centre, and the others round it about two-thirds of the distance from the centre to the corners.

The position of the view or figure can be arranged, as usual, upon the screen, which will, however, now appear to have five round holes cut through it, the Canada balsam having entirely removed all trace of "ground glass."

To adjust the focus, apply the eyepiece to the "holes," and for all practical purposes the result is a telescope, every detail will be seen with a crispness and delicacy that makes one wonder however we have previously managed to focus upon the rough surface of ground glass.

If makers would take the hint and supply the ground screen with five small polished surfaces, they would recoup themselves the extra cost by the additional number of eyepieces they would sell.

I do not claim any originality in this "dodge." It was given to me by Mr. W. Baynes, of the Torquay Photographic Society, and I have so appreciated its advantages, that I think others might be glad to hear of it.—I am, yours, &c., EDWARD J. SMITH.

Park Royd, Halifax, April 4, 1892.

PHOTOGRAPHING IN ROME.

To the EDITOR.

SIR,—In answer to G. J. J., I can say that I photographed in Rome, and have no difficulty, nor required any permit for *outside views*. For interiors a permit is required for about every building, church, palace, &c., but easily obtained from archbishops, princes, dukes, generals, &c., in charge, by calling or writing. Details for each are obtained from janitors, and a pourboire will go far to easy matters. Of Naples I do not know, but suppose it is the same as in all Italy.—I am, yours, &c., ALBERT LEVY.

Asnières, March 28, 1892.

BLACKPOOL AND NORTH-WEST LANCASHIRE ART, TRADE, AND INDUSTRIAL EXHIBITION, MAY 4 TO 28, 1892.

To the EDITOR.

SIR,—I beg to inform you that at a largely attended meeting of the Art Committee of the above Exhibition, held on Monday last, it was decided to have a section for artistic photography. This Art Exhibition, which has been held for several years, is a very successful one, and it is hoped that this decision, to include photographic art, will be appreciated.—I am, yours, &c., JOHN R. HUDDLESTONE, *Secretary.*

Winter-gardens, Blackpool, April 4, 1892.

PRINTING UNDER RED GLASS.

To the EDITOR.

SIR,—I believe it has been stated as a fact that printing under "green" glass tends to increase *contrast* in the print. Would the use of *red* or ruby glass (in place of the green) reduce contrast?—I am, yours, &c., R. MATHER.

March 30, 1892.

[It would not only "reduce contrast," but also the probability of obtaining a print at all if the glass be of the usual non-actinic kind.—ED.]

NORTH MIDDLESEX PHOTOGRAPHIC SOCIETY.—A CORRECTION.

To the EDITOR.

SIR,—Permit me to correct an error I made in reporting Mr. Beadle's demonstration before this Society. I described it as *Enlarging by Artificial Light with the Use of a Lantern.* It ought to have been "*Without* the Use of a Lantern." Thanking you in anticipation.—I am, yours, &c. J. MCINTOSH, *Hon. Sec.*

14, *Lowman-road, Holloway, April* 4, 1892.

THE WOODBURYGRAVURE PROCESS.

To the EDITOR.

SIR,—We notice a reply to James E. Gould, in your issue of April 1, to the effect that the Woodburygravure process is not patented. We therefore beg to inform you that this is an error; the process is duly patented, the specification number of which is 2211 of 1891. Perhaps you will be good enough to correct this in your next issue, and much oblige.—Yours, &c.,

WOODBURY PERMANENT PHOTOGRAPHIC PRINTING COMPANY (Eyre & Spottiswoode).

6, *Great New-street, London, E.C., April* 5, 1892.

[The "Woodbury Gravure" process to which we and our correspondent referred is not that which forms the subject of a patent.—ED.]

Exchange Column.

**** No charge is made for inserting Exchanges of Apparatus in this column; but none will be inserted unless the article wanted is definitely stated. Those who specify their requirements as "anything useful" will therefore understand the reason of their non-appearance.*

Vogel's 12×10 triplet offered in exchange for good rectilinear wide-angle whole-plate lens.—Address, WILLIAM KIRK, Cowes.

Exchange 10×8 Kinnear camera, brass bound, double and single slides, for detective camera, or 12×10 rapid rectilinear.—Address, C., 11, Waterloo-crescent, Dover.

Wanted, Adams' Ideal hand camera in exchange for a first-rate whole-plate camera, with three double backs and solid leather case, scarcely used.—Address, A. E. SMITH, 56, Schubert-road, Putney, S.W.

THE BRITISH JOURNAL OF PHOTOGRAPHY, from 1879 to present date, cloth bound, BRITISH JOURNAL PHOTOGRAPHIC ALMANACS, same years, library bound, two *Photographic News*, half calf, all new condition; wanted, photographic apparatus.—Address, G. FEVER, Sunnyside, Endsleigh-road, Ealing Dean.

Answers to Correspondents.

All matters for the text portion of this JOURNAL, *including queries for "Answers" and "Exchanges," must be addressed to* "THE EDITOR," *2, York-street, Covent Garden, London. Inattention to this ensures delay. No notice taken of communications unless name and address of writer are given.*

*** *Communications relating to Advertisements and general business affairs must be addressed to* "HENRY GREENWOOD & Co.," *2, York-street, Covent Garden, London.*

PHOTOGRAPHS REGISTERED:

H. Cooper, Northampton.—*Two Photographs of Ben Tillet.*

J. R. Jones, Crewe.—*Two Photographs of the Cheshire Beagles.*

A. P. Reid, Belfast.—*Photograph of Design of a Revolving Photographic Showcase.*

H. J. CHANNON.—Received.

REX.—The defect is due to the faulty lighting of the picture.

AJAX.—Old negatives are of little or no commercial value for their glass.

L. E.—You will find an article on the subject in another part of the JOURNAL.

W. W. W.—If you dissolve the bitumen in highly rectified benzol, your difficulty will disappear.

S. PRINCE.—Your developer is too strong in alkali in proportion to the pyro, hence your difficulty in securing density.

P. K.—Unless we knew the nature of your process, it would be impossible for us to advise as to whether it could be safely patented or not.

F. J. QUICK.—The lens would answer the purpose so long as you employed the centre of the plate only. We should advise you to procure a lens of the rapid rectilinear type.

SHUTTER.—You have evidently been over-exposing, omitting perhaps to notice that the actinic value of the light has increased enormously duringthe last week or ten days.

M. S. says: "Should be pleased if you will tell me if there is a book of photographic poses published by any firm?"—Perhaps some of our readers can furnish the desired information.

SILVER BATH.—The bath should be slightly acid; if carefully decanted, the solution will not require daily filtration. Better test the strength of the solution every day before use with the argentometer.

T. B. J.—Your burnt-in pictures are very promising, that is all that can be said for them. Much better work is being produced, a fact of which, we surmise, you are not cognisant, from the tone of your communication.

H. B.—You are already in possession of the quickest form of lens except the portrait combination of Petzval. Although this would be a more rapid instrument, we doubt if it would answer your purpose so well as what you have.

C. A. J.—It is quite against our rule to recommend any particular manufacturer's goods. There are many hand cameras now in the market, all of which are good. Send to the different makers for their prospectuses, or, better, call and see the instruments themselves.

LANCS.—Usually when new machines have to be photographed, and the best results are imperative, they are painted over with a "flat" colour of a grey tint—simply colour mixed with turpentine. This can be easily cleaned off with that solvent after the negatives have been secured.

WORCESTERSHIRE.—We cannot understand your difficulty. You must have an extraordinary kind of bitumen if it will not dissolve in benzol. We can only suggest that you obtain another sample from a fresh source, and, if that behaves the same, then change the solvent, for that must be at fault.

R. PARKER.—The orthographic lens, like the single landscape lens, will yield straight lines in the centre of the picture, but not at the margin. Hence it is not a good copying lens unless used for small plates, as compared with its focal length. For landscape purposes, or for groups out of doors, it is an excellent instrument. The price asked for it is certainly low.

RESIN.—Had you compounded the varnish according to the formula given, you would have had a good protective for your negatives. We are not at all surprised, with the large proportion of Venice turpentine you have introduced, that the "negatives become very tacky when printed in the sun." The only way out of the difficulty is to throw away the varnish and make fresh.

1870.—There is nothing novel in a silver print being as good as when it was first produced after twenty-two years' keeping. At the Photographic Society of Great Britain's rooms there are prints on view that are nearly forty years old which are still good, and show no signs of fading, although the probability is that they were produced under what would now appear to be very adverse conditions as regards permanence.

M. J. JACONS.—The best form of battery for depositing copper on a large scale, in photogravure, is either the Daniele or the Smee. The latter we prefer ourselves on account of its cleanliness, though the former is the more constant. For working on a large scale a dynamo machine is now generally employed. A machine absorbing two or three horse-power will do a large amount of work, and very economically too.

A. C. H. writes: "I am desirous of enlarging a small photograph to about thirty inches on plain matt paper for subsequent pastel work, for which the bromide papers are unsuitable. Will you please give me the formulæ for preparing, sensitising, developing, and fixing same?"—At pages 450, 483, and 487 of our volume for 1890 you will find three articles dealing most exhaustively with the subject. The pictures, however, are printed out in the frame, not developed.

STUDENT.—Yes; Dr. Jeserich's paper is published in full by the Photographic Society, but no particulars of the process he employs are given in it.

C. ALSTON inquires how he can obtain a thick film of collodion so that when it is stripped from the glass it will be about the thickness of a thin visiting card. He says he has made the collodion as thick as it can be made to flow over the glass, but even then the dried film is much too thin for his purpose.—The best method is, after the glass has been French-chalked, to surround the edges of the plate with strips of paper cemented on with gum. Then place the glass on a levelled stand, and pour on the collodion in sufficient quantity to give the desired thickness when dry.

D. BENNALL writes: "I have a batch of sensitive paper which I cannot succeed in toning, or only to a dirty red colour, and then only after a very long time. There is no fault with the bath, as another sample of paper tones readily enough in it. When the print is taken from the negative, it looks very nice indeed, quite equal to one on the paper that tones so easily. Can you suggest any means by which I can overcome the difficulty, as I have a pretty good quantity of the paper by me, which I should prefer using up to throwing away? I may say that, on putting a piece of test paper in the washing water, it was made very red instantaneously."—We recommend our correspondent to try immersing the prints, after the free silver is washed out, in a very dilute solution of washing soda for a minute or two, and then rinsing them prior to toning.

NORTH MIDDLESEX PHOTOGRAPHIC SOCIETY.—April 11, *Rural Rambles*, a Lantern Evening by Mr. J. Gale.

THE LANTERN SOCIETY.—April 11, Mr. E. W. Maunder, F.R.A.S., on *The Work of the Spectroscope as Applied to Astronomy.*

THE PHOTOGRAPHIC CLUB.—April 13, *The Choice of Lenses*, Mr. J. Traill Taylor. 20, *Masking, Vignetting, and Printing-in Clouds.* Bank Holiday outing (April 18), Godalming, Witley, &c.

PHOTOGRAPHIC SOCIETY OF GREAT BRITAIN.—Ordinary Meeting, April 12, at eight p.m. Professor C. V. Boys, F.R.S., on *Photography of Flying Bullets:* Mr. W. E. Debenham on *Relative Exposures for Varying Proportions of Image in Copying.*

THE West Surrey Photographic Society's Fourth Annual Exhibition was held last week. Several of Messrs. J. Gale's and George Davison's works were on view, and these, in conjunction with the members' exhibits, provided an excellent display.

MR. A. C. JONES has entered into partnership with Mr. Samuel J. Levi, son of the late Mr. Joseph Levi, and they will carry on, at 71, Farringdon-road, and 16, Woodbridge-street, E.C., the business of wholesale opticians, and manufacturers of, and dealers in, photographic apparatus.

LONDON AND PROVINCIAL PHOTOGRAPHIC ASSOCIATION.—April 14, *Convention Slides*, Messrs. Cembrano and Hastings. 21, Dr. Jeserich's paper on *Photography and Crime*, illustrated by slides, and *Indian and Colonial Slides.* 28, *The New Platinotype Paper*, Mr. W. H. Smith.

A NEW SOCIETY FOR THE ISLE OF WIGHT.—At a meeting held in the Town Hall, Ryde, recently, it was decided to start an Isle of Wight Amateur Photographic Association. A further meeting, to fix the subscription, is to be held. Mr. W. W. Smee, of 27, Union-street, Ryde, is the Hon. Secretary.

WE have received the annual report of the Liverpool Amateur Photographic Association, which is an excellent tribute to the continued prosperity of the Association. Accompanying the report are plans of some projected new premises which the Association is discussing the question of occupying.

A CORRESPONDENT writes: "I had my hands dreadfully stained with nitrate of silver, and during the same day, whilst working with hydroquinone and soda developer, I was much surprised to notice that my hands became pure white again. This might be a useful hint for the much-oppressed wet-plate worker."

WE recently had an opportunity of inspecting the premises of Messrs. Houghton & Son, of High Holborn, which have undergone considerable alteration and rearrangement in order to fit them for the reception of a large stock of modern photographic apparatus. Messrs. Houghton have transformed their old establishment into a most admirable depôt for the sale of the innumerable requisites demanded in photography to-day, our inspection convincing us that the firm is no way behind its competitors in enterprise and facilities for coping with whatever demands are made upon it.

*** GOOD FRIDAY.—*Will our contributors and correspondents please note that, in consequence of Good Friday falling next week, we shall go to press one day earlier than usual?*

THE BRITISH
JOURNAL OF PHOTOGRAPHY.

No. 1667. Vol. XXXIX.—APRIL 15, 1892.

ON SPOTTING.

This really very important part of a photographer's work is commonly considered of such minor consequence as usually to be ignored in treatises, occasional papers, and by the authorities generally; but a very cursory inspection of the multitude of prints distributed by amateur or professional will suffice to prove that either ignorance or carelessness governs the treatment in this respect of a large number of these photographs, and we propose to discuss in a short article some of the modes where failure may arise. It may be assumed that the professional artist may not need any hints, and usually does not, but we have seen instances where the contrary decidedly appears to obtain.

The consideration of the subject naturally divides itself into two branches—treatment of the negative and of the print. Looking first at the negative and its requirements, some individuals, fortunate in their experience, may say that with dry plates there should be no spots to treat; but this is only theoretically true. Plates are not all perfect, to start with, and they receive injuries and meet with mishaps that mar the beauty of result if not modified, and in any case suggest slovenly work. The commonest evil is the pinhole caused by air-bubbles, dust, or opaque specks in the film. And it is with them where mistakes are often made. In looking through a negative it is rare to find no pinholes; but we would here again remind our readers that many such markings need no treatment at all, and work is often most unnecessarily made for the spotter. A bright spot on a dark ground, by reason of irradiation, always appears to the eye larger than it really is, and, conversely, a dark spot on a light ground looks smaller than its actual size. Hence a pinhole quite conspicuous in size may often be left entirely alone, and be practically invisible in the print. A little experience, when observation has once been directed to the point, will soon enable any one to gauge whether the brush should or should not be applied.

Supposing it be decided to remove it, care should be taken not to let the paint in the slightest degree encroach upon the surrounding parts, or the visible mischief will be worse than ever, and great labour needed afterwards. For this kind of defect water colour is generally employed, crimson lake being a favourite with some, while others use browns or Indian ink. The advantage of the latter is its great covering power, and the fact that it will "bite" well and a half-dry brush can be employed with advantage. When larger spaces have to be covered, the usual mode of retouching is best—pencil or otherwise. We may say that the advantages of Indian ink are not thoroughly appreciated, for, if the brush has little colour in it, it can be laid on as quickly as pencil, and with greater covering power when a considerable depth of tone has to be produced. One caution is necessary, however: neither the brush nor pigment must be moistened with the saliva; if this be done, the colour clots, and will not lie evenly upon the plate. It is most desirable, in all cases, to prevent the colour from trenching upon the external margins.

Whether large spots should be taken out of the negative, so as to be as nearly invisible as possible, or blocked out entirely to print white, depends upon whether many copies are required or not. As a rule, a white spot in a print can be worked up with the brush much more quickly than the same space can be "matched" on the negative; hence, when one print only is needed, it may often be best to paint the spot opaque on the negative and do the spotting on the paper. The ease with which this is to be done depends upon the situation. Where foliage or other irregular shadings surround it, a very few touches suffice; but when the flaw comes in a flat, even surface, such as the walls, &c., in an interior, or the plain background of a portrait, far greater skill and attention is required, and no easy work attends the operation. Flaws often occur through mechanical irregularities in the film, and where this is the case it is found most difficult, and indeed often impossible, to make the colour adhere. A little projection or depression will obstinately refuse to receive any amelioration, and a spot apparently removed turns out, upon a print being obtained, to be almost worse than before it was touched. When the pigment becomes thoroughly dry, it often cracks or withdraws itself from the place. In this case there is no remedy but either to lay on a thick clot of paint (which sometimes even then fails) or to cut out the offending place with a sharp knife, and fill in the colour on the bare glass.

There is one especial point we would draw attention to. There is no doubt that nowadays a large amount of alteration of a sitter's figure or habiliments is carried out in portraiture, and to do this there is a right and a wrong way. The right way is to do the work entirely, or as near as can be, on the negative, leaving nothing for the after-spotting. The wrong way is to block out the offending part so as to print white, and then to stipple it on the print into the correct shade. The great objection to this plan is that a knowing friend may mischievously moisten his pocket-handkerchief and remove the spotting with one sweep, ruthlessly revealing the spotter's art. We have known this to be done in private albums, hence *verbum sap.* We have not exhausted our subject, and will return to it shortly.

DEVELOPMENT OF CHLORIDE EMULSION PRINTING-OUT PAPERS.

Some months ago, in a Continental Note, we quoted the recommendation of a writer in a French contemporary to obviate one of the troubles met with in printing out on the various gelatine

and collodion chloride papers, now in such general use. This was the length of time often required to obtain vigorously printed proofs, owing to the comparative weakness of the light at the time of printing. The method quoted for overcoming this drawback was to develop the faintly printed image with a solution of gallic acid in alcohol. It was said that development took place rapidly, all the fine details of the negative being reproduced.

It is quite obvious that, if the system of development above advocated—which, by the way, as we pointed out at the time, is not new in its application—were proved to have all the virtues claimed for it, the advantages of its use would not be restricted to those cases where proofs on these emulsion papers were, through lack of light or insufficiency of time, obtained in a feeble degree, but also, on the other hand, would be very welcome to a photographer who, notwithstanding the excellence of his light for printing-out purposes, might, if he were anxious to obtain a large number of collodio or gelatino-chloride prints from a given negative in a short space of time, prefer to strike weakly printed proofs from them while he had the opportunity, with the object of finishing them by development at a later hour, rather than jeopardise the chance of obtaining prints at all on that particular day. There is, in addition to these two considerations, a further one at stake, namely, the fact that it is claimed for developed prints that the chances of their permanency are greater than pictures simply printed out in the frame. This we can easily appreciate, inasmuch as the system of reduction by development is calculated to throw down the deposit in a more stable form than in the case of printing out.

Experiments made with gallic acid, in combination with acetic or citric acids, as a developer for weakly printed gelatino-chloride proofs did not, we believe, terminate so successfully as to indicate that the method was of any practical use; but the attention of the well-known experimentalist, Herr Valenta, has been turned to the matter, with results which we reproduce in another part of the JOURNAL. Here he recites the advantages which reside in the power to develop these weakly printed images at will, and also summarises some of the previous experiments with gallic acid and other substances, all of which, however, proved ineffective and unreliable. Alkaline developers also being, even in a high degree of dilution, far too energetic in their action over the unreduced parts of the pictures, were abandoned by him in his attempts.

The failure of alkaline solutions, however, led him to experiment with acid developers for the purpose, an experience with a hydroquinone-silver intensifier for collodion plates leading to the discovery that hydroquinone simply in combination with citric acid was capable of acting as a developer for weak prints on emulsion papers. With the addition of sulphite of soda this gave rise to the following formula for "developing insufficiently printed proofs on celloidin and aristo papers":—

A.—Hydroquinone	10	parts.
Alcohol	100	„
B.—Sulphite of soda	100	„
Citric acid	5	„
Water	500	„

Fifty parts of each being mixed and diluted with 1000 parts of water, and being then ready for use.

After development in this solution, which takes place in a few minutes, the prints are washed, toned, and fixed as usual. Further experiments led Herr Valenta to substitute pyrogallic for the hydroquinone when developing the images on certain papers, for which hydroquinone was unsuitable. In the various commercial papers with which he experimented, we assume that gelatine as well as collodion figures as the vehicle of the emulsion, although it is not so stated. The citric acid in the developer acts as a restrainer, and keeps the prints clear.

It is a fact of considerable value, we should think, that feeble prints on emulsion papers are amenable to development without degradation of the whites of the pictures, and with, as we also gather, no danger of any loss of tone or vigour of image. Herr Valenta's discovery that alkaline developers for the purpose are useless, but that an acid solution forms an efficient substitute is a feature of considerable practical use, which, we presume, will speedily be taken advantage of by those who are anxious to have the power of developing weak images on emulsion papers at command. We should not be surprised if their development at will did not add to the popularity of these surfaces.

Encaustic Paste.—At one time it was thought that treating the surface of silver prints with "encaustic paste" conduced to their permanence. Now encaustic paste is practically the old-fashioned "beeswax and turpentine," with which our grandmothers were wont to treat their furniture to obtain the high polish thereon. It was considered that the thin coating of wax, by resisting damp and protecting the surface from the atmosphere, would render the prints more stable. It would be interesting to know if any of the old prints recently shown at the Society's rooms owe anything to encaustic paste?

The Maddox Fund.—As we have already announced, this Fund closed on March 31. The total amount subscribed in this country is about 400*l.*, and we believe the sums received in America as well as from the Continent will swell the ultimate total to between 500*l.* and 600*l.* It has been decided by the English Committee that the sum received by Mr. Francis Cobb, the Hon. Treasurer, shall be handed over to the Doctor with a brief address stating that "the testimonial is presented to him in recognition of his services to photography, and especially of his investigations in connexion with gelatine emulsion."

Unhealthy Atmosphere.—One frequently hears complaints of the unhealthy fumes of the dark room, but evidently in the minds of some there are worse elsewhere. One day last week a photographic operator was to have attended for public examination at the London Bankruptcy Court, but did not. According to an evening contemporary, the reason assigned was "that his health would not admit of his inhaling the noxious atmosphere of the Court of Bankruptcy.' If the atmosphere of the Bankruptcy Court is worse than that of some dark rooms in which operators have to work, it must be bad indeed. Moral, avoid bankruptcy.

Register of Dark Slides.—Questions are often put as to the best way to test the register of dark slides with the focussing screen. By the following simple method, which does not appear to be so generally known as it might be, the accuracy may be tested with the greatest certainty. Place a straight-edge across the focussing screen, then pass a piece of wedge-shaped cardboard between the straight-edge and the ground glass, and mark where it touches the former. Next place a plate in the slide, draw the shutter, and repeat the operation. If the cardboard touches the straight-edge in the same point as it did with the focussing screen, the accuracy is assured. If it does not, the amount of adjustment necessary is easily measured.

Substitute for Gelatine.—Mr. R. A. Fressenden calls attention to a discovery of Messrs. Cross & Bevan (whose names

are familiar in connexion with the primuline process of photography) which indicates a mode of preparing a substance which "strongly resembles gelatine in appearance, flexibility, and odour when burnt, and might, on account of its solubility in ammonia, be of use for photographic plates." They formed this new substance by treating cellulose with dilute nitric acid, thus forming oxycellulose. This substance is soluble, on digestion, in ammonia, and on evaporating the solution a transparent film is left, which, by its odour when burnt, seems to be a nitrogen compound of cellulose. We are not aware of any use having been made of this discovery in photographic directions, but upon a first glance there would really seem to be a valuable field for it if all that is described be correct, and there be no special difficulty connected with its manufacture.

Photographing the Boat Race.—Seldom, if ever, have photographers had such an opportunity for securing really good pictures of the boat race as they were favoured with last Saturday. The weather was charming, while the light was all that could be desired. Never before were so many hand cameras to be seen amongst the crowd who lined the banks of the river last week. Perhaps no two university crews have been so much photographed as have the present ones, for during the whole time they were practising hand cameras seemed to be constantly on the spot. Persons taking hand cameras into crowds should be particular how they carry them. We were told of an amusing circumstance that occurred at the boat race last year. A gentleman took with him a hand camera with cut films, which, when not in use, was slung by a strap at the side. On returning home, he was surprised to find that the index registered about three times the exposures he had made. He then discovered that some practical jokers in the crowd had been manipulating the instrument without his knowledge. This might easily be done without detection in any crowd, particularly a moving one.

Reduction of Patent Fees.—In introducing the Budget on Monday evening last, the Chancellor of the Exchequer said: "My right hon. friend the President of the Board of Trade has informed the House of his wish to see the heavy charges for the renewal of patents reduced in the interest of the poorer patentee, and for the further development of inventions. Small as my margin is, this is a reform which the Government do not wish to delay, and which they think they can afford. The primary fee of 4*l.* now charged for the first four years will remain, but from the end of the fourth year onwards large reductions will take place. At present the fee for the next four years is 10*l.* a year; this will be reduced to 5*l.*, 6*l.*, 7*l.*, and 8*l.* For the fifth and sixth year the present fee is 15*l.* a year; this will be put at 9*l.* and 10*l.* For the next four years, instead of a charge of 20*l.* per annum, the fees will be 11*l.*, 12*l.*, 13*l.*, and 14*l.* These reductions, which, I believe, will be received with extreme satisfaction by a very large class, will ultimately involve a loss of about 50,000*l.* a year, but we should not ask that the new scale should come into operation before September 24."

Swollen Apparatus.—Just now apparatus that has been stored away through the winter months is being brought to light again. It is often found, if it has been kept in only a slightly damp place, that the wood has swollen sufficiently to materially interfere with the free movement of the sliding portions. Shutters of slides for instance, are difficult to withdraw, and other working parts are hard to move. Especially is this the case with some of the cheaper forms of apparatus, which, as a rule, are made of imperfectly seasoned material. Frequently, when this trouble is met with, recourse is had to a piece of glass or to glass paper to scrape away the wood, until the part works easily. This is a great mistake, as it often proves a source of future trouble; because, when the wood shrinks again, as it will do, it no longer fits. We recently saw some dark slides, the shutters of which had been subjected to this treatment two or three weeks back, that were almost worthless for use in a strong light. Had the slides been simply allowed to remain in a dry place for a few days, they would have righted themselves. Plumbago is an excellent lubricant for the sliding portions of woodwork, and is the one generally used. It has, however, the disadvantage of soiling everything it comes in contact with. It is not generally known that powdered talc—French chalk—answers the purpose quite as well, and, of course, is much more cleanly to use. Sometimes the folds of a camera bellows are prone to stick together. This may be entirely remedied by rubbing them over with French chalk. This material possesses many virtues in connexion with photography and its appliances.

Reproduction of Feeble Negatives.—It is no unusual circumstance for a negative that may be excellent for one purpose to be next to useless for another. For example, a negative may be thin and veiled and yet yield a fairly good print on albumen paper, or a vigorous one on bromide paper, but it would be worthless for some purposes, say, for instance, a Woodburytype relief. If the negative be a valuable one, few would care to risk its intensification, which might render it unsuitable for its original purpose. In such a case there is nothing left but to reproduce it, and then comes the question of the best method of procedure? It is pretty generally accepted that, for the reproduction of negatives, either same size or enlarged, carbon transparencies are the best in practice. Unfortunately, however, thin negatives are not well adapted for vigorous carbon transparencies, when made in the usual way on the tissue specially supplied for the purpose. The difficulty may, however, be overcome in the following manner. Instead of using the specially prepared tissue select one that contains much less pigment, such as those used for paper prints. Then the shadows will be formed of a greater thickness of gelatine, although they may seem less dense than if the former were employed. Now, with such a transparency it is easy to obtain almost any degree of density by simply treating it with a solution of permanganate of potash. By this method of intensification it is the gelatine that is acted upon and not the colouring matter, as in the case of a silver image. The colour conferred by the permanganate has the advantage of being of a highly non-actinic character. Having got a strong transparency, it is a very easy matter to obtain a vigorous negative by almost any process.

VARIATION IN COLLODION EMULSION WORKING.*

The strength of the final sensitising bath, it may be remarked, may be varied with advantage according to the treatment to which the plates are to be subsequently treated as regards development and other circumstances. For instance, if they are to be used wet, with excess of silver and iron, and silver or acid pyro and silver development—in fact, as ordinary wet plates—the strength of the silver solution should be at the maximum within the limits we have given, or, if the highest degree of sensitiveness is required, with alkaline development; but, for moderate rapidity, under the latter form of development it will be found more convenient to employ the solution weaker, as the necessary removal of the excess will be more easily effected, and the chances of fog or abnormal reduction greatly decreased. It must be clearly borne in mind that, when alkaline pyro or any of the similar methods are employed, the film must be absolutely free from the slightest trace of soluble silver salts, or the inevitable result will be the production of dense fog immediately the developer is applied; but, when the reducing agent is used in the acid state, the free silver forms a necessary adjunct to the developing process.

When the plates are to be used without the removal of the free silver, it is, perhaps, necessary to exercise a little more care in the composition of the sensitising bath than is the case otherwise; so far at least as the employment of a plain and clean solution, and not an old printing bath or similar substitute, is concerned. The acid developer is far more liable to set up abnormal reduction than the alkaline, and to produce stains and markings, more especially with imperfectly cleaned glass. A glass plate that would successfully pass the ordeal of alkaline development might be hopelessly stained and smeared if submitted to treatment with iron and silver. Beyond this, however, the silver development method presents no difficulties, and the routine is practically identical with that of ordinary wet plates.

The very finest results as regards quality, though at the expense of a certain increase of exposure, are obtained by means of the pyro and silver developer. The character of image so obtained very closely

* Concluded from page 228.

resembles the old style of pyro-developed films of iodide of silver not only in the richness and vigour of the deposit, but also in beauty and variety of colour; but the tendency to harshness or excessive contrast is wanting. For transparencies, opals, or photo-mechanical and similar purposes, the pyro developer is certainly to be chosen, and the formula may be as follows:—.

Pyrogallic acid	1 grain.
Glacial acetic acid	20 minims.
Water	1 ounce.

This will keep in good condition for some days; in fact, is all the better for having been made at least twenty-four hours before use; but it should be thrown away as soon as it becomes at all discoloured. There is no occasion for any further complication in the shape of additions of alcohol or other matters to the solution, as the acetic acid suffices perfectly to make the developer flow smoothly.

The plate, after sensitising, is allowed to drip until the greater part of the superfluous solution is removed, and is then drained for a few moments upon a slip of blotting-paper, or the latter may be drawn gently along the lower edge of the glass where the drainings have accumulated, and the plate is then transferred to the dark slide for exposure. This should be preferably of the old single wet-plate type, with silver-wire corners, as, if all four edges of the film are in contact with the rebate of the ordinary dry-plate slide, it will be next door to an impossibility to develop an image free from stains; besides which, the contact of the silver solution with the woodwork of the slide not only unfits it for use with ordinary dry plates—unless thoroughly cleaned—but rapidly deteriorates or destroys the slide itself. It is always well to insert a strip of blotting-paper in the lower rebate of the slide to absorb any drainings that may accumulate during exposure.

With regard to the length of exposure requisite, no definite guide can be given here, beyond saying that, with pyro development, the plates may be reckoned as equal in sensitiveness to a somewhat slow wet plate, or, if iron be used, to a rapid wet plate; some care must be devoted to the study of what constitutes a correct exposure, as silver development affords little or none of the "latitude" to which modern dry-plate workers are so prone to trust.

The exposure having been made, the plate is taken from the dark slide by means of a pneumatic or other holder, if the fingers are to be kept clean—for it must be remembered that it was to wet-plate development chiefly that the photographer of a past generation owed his reputation for dirty hands, and the art itself its descriptive cognomen of "black"—and a small quantity of the developer poured quickly and evenly over the surface. In the performance of this simple operation some little skill is necessary in order to get the solution evenly and quickly over the plate. If it be dashed on roughly on one part of the plate, the silver solution will be washed away from that portion, and a patch produced, in which the density and detail are less than elsewhere. The solution should be poured gently but quickly along one edge of the plate, which is, at the same time, gently inclined, so as to cause the developer to flow in an even wave over the whole surface, and then backwards and forwards with a rocking motion. To those who have been accustomed to development in a dish this will at first probably present some difficulty, but it rapidly disappears with a little practice.

The quantity of solution employed, too, forms a matter of some importance, since it must be duly proportioned to the quantity of silver nitrate retained on the surface and in the pores of the film, and upon which the formation and density of the developed image depend. Here it may be well to point out, for the benefit of those who are not aware of the fact, that the image obtained by this form of development is produced at the expense of the silver remaining in the free state upon and in the film after its removal from the bath, and not as in the case of alkaline development, by the reduction of the silver salts forming the film. Clearly enough, then, with a given quantity of silver nitrate clinging to the film, it is necessary to limit the quantity of the reducing agent in order to obtain a certain result. The more concentrated the developer—that is, the smaller the quantity of solution used—the more vigorous will be the resulting image, and *vice versâ*, and it is well to bear this fact in mind when making negatives for special purposes.

The action of the developer proceeds very rapidly, much more so than in the case of a gelatine plate, and requires careful watching. The shadows and half-tones should remain quite clear and distinct by reflected light, and the progress of the development should be watched and judged by examining the plate by transmitted light, and stopping the action as soon as the requisite density is secured. If the exposure has been correct—and here we must repeat the necessity for accuracy—density and half-tone will be secured simultaneously, and without trouble; but, in the case of under-exposure, the density will come before the finer details, and hardness will result, while under opposite conditions there will be a want of vigour and contrast. The first fault is irremediable, but the second may be overcome by intensification. Two or three drops of the silver solution are added to the developer that has been already used, or a fresh quantity may be taken, adding, in that case, a little more of the silver; and this is applied to the film until the requisite density is attained, after which the plate is well washed and fixed.

For quicker exposure the pyro must be replaced by ferrous sulphate, which, while it acts more rapidly and with a shorter exposure, gives a more metallic-looking image by reflected light and less vigour by transmitted. The strength of the solution may be varied within pretty wide limits, according to circumstances, but the best "all-round" formula for general work is

Ferrous sulphate	20 grains.
Glacial acetic acid.....	20 minims.
Water	1 ounce.

There is very little difficulty nowadays in procuring sulphate of iron of the best quality, so that we need not repeat the advice of years back on the selection and treatment of the salt. It is simply dissolved in cold spring or tap water and the acid added after solution, the whole being then filtered. This is better for having been made a day or two, but if required for immediate use the iron may be dissolved in hot water and rapidly cooled after the addition of the acid. The same rules apply to the use of the iron developer as to pyro, the only difference between the two being in the matter of rapidity of action. For intensification, however, when necessary, the pyro solution is preferable to that of iron, or, if iron be the more convenient, then an addition of citric acid should be made instead of acetic, say a grain to twenty grains of iron.

Various additions to and modifications of the iron developer found favour with photographers of a past era, but it is questionable whether they conferred any but merely fancied benefits. The substitution of the nitrate and acetate of iron for the sulphate, or, what was equivalent, the addition of certain salts to bring out the formation of these new compounds, was amongst these; but, as has been said, the advantages were dubious, a remark that may be extended to the addition of various salts of copper and of other metals, the real object of which was scarcely clear. There is, however, a strong possibility that, by the use of various organic matters added to the developers, such as sugar, gelatine, and similar substances, decided benefits may be secured in the way of clearness and vigour where those qualities are of especial value. But it would occupy too much space to enter into a lengthened discussion of such matters here.

The majority of our readers will, no doubt, in working the auxiliary bath emulsion process, prefer to adopt the more modern style of development with pyro, or one of its analogues, and alkali, if it is only because it is the more familiar process to them. The results are equally good, the sensitiveness as great, or perhaps greater, under some conditions, and the risks of failure are considerably less.

ON THINGS IN GENERAL.

Mr. Phillips, in his last note, does not bear upon the original point of discussion, which was, as to whether or no Messrs. Hurter & Driffield had forgotten what they had written. He, in effect, reduces the matter to a burlesque on a well-worn quotation from a popular comic opera, "What, never?" "Well, hardly ever." "Almost identically the same" is without meaning in a scientific question. The whole body of photographers, with scarce an exception, understoood Messrs. Hurter & Driffield to hold that ratio of

gradation could not be influenced by variations of development; but, when such a view is questioned, they, to the astonishment of almost every one, write to say that they do not hold such views—"well, hardly ever." Who does the jugglery?

One of the most valuable papers of a practical nature ever read at the London and Provincial Photographic Association (or elsewhere) was that of Mr. Rawlings on *Photographing on Wood*, and the more praise is due to him on account of the fact that his method is open to any one, he having left it entirely untrammelled by patent. One great advantage of this method is the pleasant surface it offers for use with the pencil, owing, no doubt, to the free use of zinc white, one of the properties of that pigment being the agreeable surface it gives for pencilling. It is possible that the Chairman was right in his suggestion that the sensitive surface was carbonate of silver produced by the action of the zinc white on the nitrate of silver. There are, however, two objections to this theory. First, the fact that carbonate of silver is usually supposed to be very slowly acted upon by light, except in the presence of ammonia; and, secondly, zinc white is, theoretically, an oxide, and not a carbonate of zinc, though there are those who hold that it is commonly adulterated with carbonate of lead to give it body, a statement I should not be inclined to give credence to.

Mr. Chadwick's letter in the same number of the JOURNAL in which the report on Mr. Rawlings' paper appears is an interesting contribution to the popularising of knowledge of the human eye; but why does he use the term "sensitiveness" with regard to the yellow spot? The yellow spot, or the central spot, or pit, as it is sometimes called, is not the most sensitive part of the retina, if we are to use the word in its ordinary acceptance. Owing to the much finer organization at this part of the retina, the bacillary layer in it consisting of cones only, far smaller and much more numerous than in the surrounding part, their diameter being about the ten-thousandth of an inch only, there is a far greater "distinctness of vision," or, as Fuellen terms it, in his book of test-types, "acuteness of vision;" but not of sensitiveness. That characteristic is found in a zone considerably removed from the *fovea centralis*.

I am afraid that the subject "Why photographs fade," so well treated of by Mr. Herbert Starnes, will still remain an enigma for long years to come. Mr. Foxlee did well to accentuate the fact that complete fixing was more important than thorough washing. Hypo in the print has been solely held out as a thing to be avoided like a pestilence, that its true position is rarely understood, and at the present time it has become a complete fetish. It is not so much the hypo in the print that has to be eliminated as it is the product of hypo and silver chloride being allowed to assume a dangerous form that is to be provided against. Such safeguarding is most probable when plenty of hypo acting for a sufficient time is used. I possess hundreds of prints on albumen over a score of years old that are as good now as on the day they were printed. Also I possess a great many of which an entirely opposite character could be given. I have developed silver prints of the same age on paper which give decided traces of fading. When atmospheric influence and the effects of improper mounts are excluded, my opinion is that a properly fixed and washed print on albumenised paper is practically permanent.

What a remarkable, and, to an old hand, refreshing, thing has been the unexpected appearance—in one month too—of two papers on wet collodion, from the pen of experts. An old photographer once said in my hearing, to a recent amateur who was complaining of his difficulties with dry plates, "Bless your life, sir, you don't know you are alive." And much truth there was in the observation. I wonder how many of the photographers, now so glib with their experience of processes, would care to practise the art for a single day if they had to pass through the experiences of a collodion man of days almost gone by.

Ah, those were negatives. I have seen, and I hope I have made, some good dry-plate negatives; but the general average of quality of, say, a dozen good dry-plate negatives is not to be compared to that of an equal number of good wet plates. What printing qualities they possessed! What rich tones and juicy shadows! But I do not regret their departure; to go back to the old work would be like a nightmare.

Such recollections make one turn to the recent work of a very old hand at the camera, Mr. Vernon Heath. His work, which I have not yet had an opportunity of reading, is evidently highly interesting in its vivid accounts of the difficulties surrounding the work of the old *régime*. A good negative, taken under the difficulties he will describe, was a thing to be proud of. Nowadays there are few beginners even who have not produced some excellent plates. The regret for the old gives way to thoughts of the pleasure the new has given to hundreds, nay, thousands, of practitioners of our art, so fruitful in producing good cameraderie.

FREE LANCE.

THE FADING OF SILVER PRINTS ON ALBUMENISED PAPER.

[Photographic Society of Philadelphia.]

THE fading of silver prints on albumenised paper is an interesting matter, but one about which we know very little. Those of us who have given the subject any attention have been struck with the singular fact that skill and care on the part of the maker of the prints is no guarantee of their permanency. In fact, numerous cases could be quoted where prints made in the most slovenly manner, with poor materials, and by men so ignorant that they hardly knew the names of the chemicals handled, have actually outlasted the best efforts of skilled and careful photographers.

In most other departments of practical photography we could say that more careful investigation would help us in determining the causes of fading, even if it proved impossible to entirely do away with them; but the subject is an exceedingly difficult one, partly owing to the complex chemical nature of the silver print, and partly from the impossibility of watching the behaviour of batches of prints, or even of individual prints out of a given batch, for years at a time, and of obtaining data as to their manufacture which would be of any practical value.

From the earliest days of silver printing imperfect removal of the hyposulphite after fixing has been cited as a pregnant cause of fading. Although I do not mean to inculcate any carelessness in the operation of final washing, I am satisfied that the dangers from the said source have been much overrated. Assuming that a good commercial sample of the hyposulphite is used, and that no foreign matter like acids be allowed access to the fixing bath, there is really no reason why a print should not last well, even if quite a large quantity of the fixing salt remains in the paper. Of this fact I am certain.

I have seen prints made by an experienced maker of albumenised paper, which had merely received a couple of rinses after fixing, and were then immediately dried. These prints were several years old when I saw them, and had remained perfect in every respect. This gentleman agreed with me in condemning the excessively long soakings and washings then customary, sometimes lasting for four-and-twenty hours. Experiments made after my interview with him bore out his statements to my perfect satisfaction.

I will now ask your attention to a point in silver printing which I have been led to believe has an influence upon the permanency of the print, and one which I do not remember to have either read or heard mentioned. Let me say, however, that I do not advance it as a universal cause of fading, but as one of the ways in which an explanation may be given of the wonderfully contradictory behaviour of prints from the same batch, made in the same manner.

Every one who has tried silver printing is aware that even the successful toning of the print cannot be accomplished if there is free nitrate of silver left in it, but that the said salt must be washed away before the print is risked in the gold bath. Neglect of this means red patches and streaks, alternating with ashy blue tints and mealiness over the entire print, and oftentimes precipitation of the gold in the bath, and consequent stoppage of the toning action. But this is not all.

The proper forming of the image on a silver print demands the harmonious chemical action of three distinct compounds of silver: the first, chloride of silver; the second, the organic colorific compound of albumen and nitrate of silver; and the third, free nitrate of silver in excess. When a print is taken from the frame and washed, the chloride and a certain portion of the darkened organic compound remain unaffected, while the free nitrate, and in all probability a considerable amount of the organic compound, are washed away. Now, the point I desire to ask your consideration of is, whether the too complete removal of this organic compound, in the washing before toning, may not injure the stability of the print by robbing it unduly of one of its important component parts before the gold has had an opportunity of depositing upon it and ensuring its permanent abode in the print. The objection may be raised that the hyposulphite would remove it in the fixing, but if the gold is well deposited upon it it would remain.

I am aware that this idea may seem far-fetched, but we can find analogies to it in several departments of photographic chemistry. Take, for instance, the manufacture of washed collodio-bromide pellicle. Here the bromide of silver is formed in the collodion by adding nitrate of silver to collodion containing a soluble bromide. In order to get rid of the lye salts which come from the double decomposition between the bromide and the nitrate, the emulsion, after setting, is washed in water to remove them. But it sometimes happens that the pyroxyline is of a variety that will not bear the washing without parting with an organic compound between the silver and the pyroxyline, which seems to form during the ripening of the emulsion. When such is the case, the resulting pellicle gives thin, foggy negatives, and is in every way unsatisfactory.

It was long ago discovered that nitrate of silver reacts with such substances as albumen and gelatine (less so with pyroxyline), entering into combination with them; and, as I have already said, the albumen compound is the important colorific substance of the silver print. Another fact that seems to help in bearing out my idea is, that prints from which all traces of silver are thoroughly eliminated, as, for instance, by prolonged boiling in some chlorinous solution, refuse to tone.

We are therefore driven to the conclusion that prints must contain an appreciable quantity of silver in order to take the gold properly during the toning; but, on the other hand, we know that an excess of the silver is incompatible with good toning, as I have already remarked. It may, then, be fairly asked how long the prints ought to be washed before the toning, and the answer to this question can be found only in practical experience. A batch of, say, 150 8×5 inch prints put into one of the largest porcelain pans obtainable at the stock dealers, and set under an ordinary dark-room tap, would contain a large amount of free silver after half an hour's washing, while a dozen prints of the same size would probably be ready to tone after ten minutes' immersion, or less.

But another objection may be raised. The question will be asked why some prints from every batch fade in a comparatively short time, while the rest remain white for years and years. Now, to answer this, I must ask you to remember that, excellent as our commercial brands of albumenised paper are, it is, nevertheless, an impossibility to coat sheets with albumen so evenly that it shall be of just the same thickness or body at every part of the sheet. The behaviour of the prints, both during the printing and after they are finally dried, proves this. Every practical printer knows the value of the thick ends of the sheet, and, if he is a careful workman, reserves them for the most difficult subjects. Prints made on these "thick ends" will curl in a refractory manner when dried, owing to the heavy body of albumen on the paper, while those made on the more central portions of the sheet remain flat.

Remembering this, is it not fair to assume that prints, even when made from the same sheet of paper, will not part with the organic silver compound equally when washed before toning, owing to the variable thickness of the albumen, and will thus present to the gold a variable quantity of the important organic constituent?

Before proceeding further, let me say that I hope this theory is not a tenable one, for, if true, I do not see how things could ever be improved or rectified. I am afraid, however, that there is some truth in it. The fact that prints toned in the chloride of lime toning bath, without any washing whatever to remove the silver after coming from the frame, last fully as well as others made in the usual way (better, indeed, in some cases), is another item in support of the view I advance.

An enumeration of all the possible causes of the fading of silver prints would be indeed lengthy; but I wish to direct attention to the want of reliability of a mountant which, until very recently, I had always considered quite safe, and have myself largely used. I refer to gelatine, either when dissolved in water alone, or in water with alcohol added to prevent cockling of the mount—not only as a mountant in the usual sense, but also, I regret to say, as a material for cementing prints to glass, or as a sizing. My attention was first directed to this by an able editorial in THE BRITISH JOURNAL OF PHOTOGRAPHY, in which the statement was made that there had been complaints made of the beautiful "cemented prints" fading in a surprisingly short time. I had scarcely read this article when I became aware that a handsome frame full of cemented prints owned by this Society showed unmistakable signs of fading, and when I last saw them they were in very bad case. Prints of my own, made with the greatest care and best obtainable material, have behaved in the same manner. I am also informed by one of Philadelphia's oldest and most learned photographers that a particular style of print in which he used gelatine in one of the finishing processes has not lasted as well as he might have expected after the great care expended upon them; and the same gentleman strongly condemned the mounting of prints on cards with gelatine in any form, preferring starch. My own experience goes to the support of this statement in the most positive manner. Prints that I have had by me for more than twenty years, and mounted with starch, have lasted well, while almost every gelatine-mounted print in my possession has faded more or less, according to its age. I am the better prepared to say this from the fact that I have within a few days carefully examined the contents of a portfolio that had been laid away for many years.

If I were asked what are the important matters to care for in printing, as regards permanency, I should reply: A good albumenised paper, *free from smell*, worked in as strong a silver bath as the salting of the paper would allow, toned rather rapidly after the minimum of washing, and, if necessary, adding common salt liberally to the toning bath to make up for it; to wash off the gold thoroughly before fixing, and to have the fixing bath strong and lukewarm to the finger; to work the prints about thoroughly during the fixing and the first rinses after fixing; to wash them in rapid changes of water; to avoid gelatine as a mountant, and, finally, to rub in wax after rolling, the best means being to reduce pure white wax to the consistency of soft butter with turpentine and a little oil of lavender. I prefer this to the ordinary burnisher.

ELLERSLIE WALLACE.

THE EARLY DAYS OF ANIMAL PHOTOGRAPHY.

(JOURNAL OF THE CAMERA CLUB.)

THE slides which are presently to be brought before you on the screen are some of the results of the first photographs of wild and other animals taken systematically, many of them dating from the year 1864, and I think you may be interested if I say a few words about the early days of animal photography.

Wishing to try to produce a series of photographs of wild animals, I endeavoured to learn what had been previously accomplished in this direction, and could not find that any such work had been carried out by anybody in any country; the only person I could hear of as having done anything at all in this branch of photography was the late Count de Montazon, who had taken some negatives at the Zoological Gardens. Having received, through Dr. Sclater, the requisite permission to instal myself at the Gardens, and finding I could reckon upon the able assistance of Mr. Bartlett, so many years the Superintendent, I began with a few trials, which gave sufficiently good results to show me that I was not undertaking too much, and also taught me that it was necessary to proceed methodically, if any work of use was to result. I decided that to be of any value for publication, nothing would be as interesting and useful as stereoscopic pictures: firstly, because only in the stereoscope can the real form of an animal be seen—no single picture will show anything approaching the beautiful effect thus obtained, not even on the screen; secondly, it was only this way the animals could be seen away from the bars, behind which, it was certain, the greater number would be taken, as in those days they were not the open dens and roomy spaces of later years. As there is at present a revival of stereoscopic photography, may I, as having seen the flow, high tide, and dead—very dead—low water of stereoscopic work, here speak of what, in my opinion, caused such a complete stoppage of this beautiful and valuable branch of photography, that to-day many grown and educated persons have never seen a stereoscopic picture. One cause was the fatal error, I believe of French origin, of making the pictures too large (it must be understood I am only referring to the lenticular instrument), and, therefore, mounting the same points of the pictures at such a distance apart that the normal pair of eyes could not combine them. Other causes also had much to do with driving it out of fashion. The unnecessarily high magnifying power and inferior quality of the lenses, which strained the eyes, the incorrect way the instruments were made, the great difficulty in illuminating the pictures when being examined, and carelessness in not reversing the prints when mounting them, or even sending them out with both prints alike. In these days of "You push the button, and we do the rest," the public soon tires of anything that is troublesome to work. I know only one really good instrument, and this was invented by an uncle of a member of your Club, and was the outcome of an accident. Returning to our subject, the next step was the question of the size of plate. It was then usual to use patent plate glass: this was settled to be 7½×4½ inches, as giving plenty of space for the size required, and allowing draining room for the silver solution. The late Mr. Dallmeyer advised me to use portrait lenses, and those selected were his No. 1 n long focus, and were carefully paired. In 1891 you have a variety of lenses to choose from, of almost every conceivable type; yet I think, were I now going to take more of these photographs, I should prefer the kind I used in 1864. I

do not want so-called depth of focus, but prefer a lens which I can use at a very large aperture, which gives me the object exceedingly sharp, and the surroundings rather out of focus. You will presently see that I could not always do what I wanted. I usually used what was then known as Stop No. 2, and sometimes No. 3. I cannot tell you the diameter in focal measurements. Of course, the only method of working in those days was wet collodion, and younger photographers can have very little idea what it meant to run an animal about in its enclosure on a broiling hot day, endeavouring to tire him out; then rush off, shut yourself up in a close tent to prepare your plate, coming out with eyes watering from the ether vapour, to find your subject refreshed by the interval of rest, and having to commence *de novo*, knowing your plate was rapidly spoiling. Just compare this with the present dry-plate working; no such things as dry plates, orthochromatic or otherwise, were then known, no developing at home whenever you liked, and none of the many valuable improvements and inventions which are to-day at your command. The exposing of the plate was done without any of the elaborate paraphernalia at present so much in vogue—no shutters of one-hundredth or five-hundredth of a second, they would not have been of much use; no india-rubber balls and tubes, delicate pneumatic brakes, pistons, or roller blinds; only the sweet simplicity of a flap shutter, moved by the thumbs and fingers, by which an exposure of a quarter to a fifth of a second could be given. I had no finder, and in those days the focussing glass was not even hinged to the camera, but had to be removed to allow the dark slide to take its place. Of course, the camera was mounted on a tripod; a hand camera was not used, for the excellent reason that the instrument had not then arrived at that stage of progressive development.

Many of these plates were kept over half an hour in the hot open air. The work could only be attempted on bright, clear days, and I could not do that which has been so strongly recommended—expose always without sunshine. I do not like the principle of long exposures for animals, as I have never seen them quiet for one second in a position I should care to take; neither do the very rapid exposures of other workers please me. I see little utility in taking animals in motion, unless for such experiments as those so elaborately and exhaustively carried out by Muybridge and others; but I like to see a lively, bright look about an animal, with its attention attracted or arrested. This brings me naturally to the concluding portion of my remarks this evening. What should be the position of the animals, settled in my mind as the best, in which I should endeavour to photograph them? I am well aware very much has been said here and elsewhere on this subject, and perhaps many present will not agree with the view I am going to speak about. However, when these photographs were taken, very many of the best known names as photographic workers at present were perhaps thinking more about toffee and tops than of photography, and I had the great advantage of not having to decide where doctors differ. I concluded, then, that the best position, where only one was wanted or could be taken, was always in profile; and the more I see of later work, and the more I observe animals, the more convinced I am of the correctness of my determination under the above condition.

In this I am thoroughly backed by a gentleman, whose acquaintance I have only made within the last few weeks, who brings to bear upon his splendid photographs of horses and other animals an unrivalled knowledge of horseflesh, having for many years studied and practised, not only as a veterinary surgeon, but also as a horse-breaker, tamer, and dealer. His books on horses may be known to some of you—I refer to Captain M. H. Hayes. I have not the honour of being in any way connected with this very genial and modest photographer and gentleman. I made his acquaintance after hearing his lecture on horses at the Polytechnic, and, in conversation with him shortly before he sailed for South Africa, he made a remark about position I thought conclusive. Said he, "How do you place a horse or a dog if you want to look at him with the idea of either buying or selling? Why, in profile, and in no other way; and, when you have had a good profile view, you walk round him and look at details." He further says, there is no other position in which any comparison of any value can be made between similar animals. Having secured the profile, there can be no possible objection to photographing your subject in full details, from the muzzle to the tip of the tail; its hoofs, feet, horns, eyes, ears, the front, back, or any other view, and many of these would be of great value. I am not going to show you all profiles; I had no chance of being able to do so. Having no predecessors in this work, I had nothing to indicate to me the safe road, neither beacons to warn me of the points I should avoid. I was obliged to feel my way very cautiously, and try to work up to a certain standard fixed in my mind, using a great love of animals and a slight knowledge of horses to assist me, and I must ask you not to judge by the present standard the work of the earliest days of animal photography. I should mention that many of the slides were made twenty-six years ago. As the photographs are shown, I will say a few words about any that I think will interest you, and shall be pleased to reply, to the best of my ability, to any questions any one present may wish to ask. FRANK HAES.

[The slides shown included photographs of seventy-five animals, mostly wild ones, and a few reptiles; among them—Jumbo in his youth, his friend Alice, who was burnt in the United States, the zebra that Rarey tamed *pro tem.*, the first zebra foal born in England and its dam. Winners of races: Caractacus, Diophantus, Favonius, and Hannah. A slide of the dromedary standing at rest, to show that the natural position of the legs is the same as that shown by the horse, zebra, antelope, or rhinoceros. A portrait of the aye-aye of Madagascar, the first one seen in Europe, and also one of the sable antelope, known previously by skin and horns only.]

DEVELOPMENT OF INSUFFICIENTLY PRINTED PROOFS OF CELLOIDIN, OBERNETTER, ARISTO, MIGNON, AND SIMILARLY PREPARED PAPERS.

[*Photographische Correspondenz.*]

Of all direct printing papers the so-called gelatino-chloride and collodio-chloride of silver papers are those which are the most sensitive, they printing in one-half and one-third the time of sensitised albumenised paper. Yet it may be desirable to still shorten the time required for printing these papers, especially on foggy winter days, not losing sight, however, of the fact that any result, to be of any practical value whatever, must bear comparison in tone and general richness with the best of silver prints.

Of the advantages of employing a good developer for bringing out insufficiently printed proofs there are many. 1. The time used for printing may be shortened to a quarter, or even one-fifth, of that necessary to give fully printed proofs. 2. When daylight is not readily obtainable, it is possible with artificial light, such as that produced from magnesium powder, to produce prints of a beautiful warm colour. 3. It is possible by this process to obtain tones which fully printed proofs, without development, can never give. 4. Finished prints of an agreeable tone may be readily produced from insufficiently printed proofs showing the slightest impression of a picture only, as well as from those which have been almost fully printed out.

Experiments for obtaining a developer suitable for papers ordinarily used for printing out there have been but few, and these have been restricted to the employment of gallic acid. Formulæ of this description have been published by Liesegang* (gallic acid, tannin, acetate of soda, and water), Lebedzinsky,† Legros,‡ and others.

Der Amateur Photograph§ reports a similar process, recommending as a developer a concentrated solution of gallic acid, neutralised with bicarbonate of potassium. All these baths act after the manner of the gallic acid developer known for the last thirty years for making enlargements on salted papers.

Developers containing gallic acid are more or less liable to turn bad; they often produce on the prints a muddy deposit, and cannot be successfully used for all brands of paper alike. Often also I obtained on papers otherwise suitable tones which did not satisfy me. For these reasons I commenced to look about for a developer not liable to these defects, which would keep at least for some days, and suit most of the brands of printing-out papers at present offered to the trade. My experiments have been made on the celloidin paper manufactured by Dr. Kurz of Wernigerode, Obernetter paper, mignon paper by E. Büchler of Mannheim, "l'apier au citrate d'argent," by Lumière, and aristo paper of an unknown make.

At first I tried alkaline developers, but these proved totally unfit, they producing total reduction of the silver all over the paper, even if very strongly diluted. An exception to this was the hydroquinone soda developer of Baron von Hübl, recommended for his collodion emulsion dry plates. Mixed with a sufficient quantity of bromide of potassium, this developer gave, on Dr. Kurz's celloidin paper, fairly good results. Copies, however, showing, to commence with, a very faint impression only, could not be developed without a muddy deposit making its appearance.

Distilled water	1000 parts.
Gallic acid	4 ,,
Citric acid	6 ,,
Acetate of soda	20 ,,
Solution of citrate of lead (1 : 10)	15-20 ,,

To be filtered (will keep about eight days).

‡ *Bulletin de la Société Française de Photographie*, 1891, page 152.

§ *Allgemeines Anzeigeblatt für Photographie* (1892), p. 20.

‖ A. Soda

	40 parts.
Sulphite of soda	6) ,,
Bromide of potassium	4 ,,
Water	200 ,,
B. Hydroquinone	10 parts.
Alcohol	100 ,,

Ten parts of A are mixed with from three to four parts of B, and diluted with forty parts of water.

I therefore commenced experimenting with acid developers, starting, n the first place, with Baron von Hübl's hydroquinone intensifier for collodion plates. It consists of a solution of silver, and a solution of hydroquinone, five parts; water, 500 parts; and citric acid, 2-5 parts, the latter solution acting on celloidin paper by itself as a developer.

Further experiments showed the advantage of an addition of sulphite soda, and were the foundation for the following formula for developing insufficiently printed proofs on celloidin and aristo papers:—

A.	Hydroquinone	10 parts.
	Alcohol	100 ,,
B.	Sulphite of soda	100 parts.
	Water	500 ,,
	Citric acid	5 ,,

Fifty parts of A are mixed with fifty parts of B, and then diluted with 1000 parts of water.

This developer acts clearly and clean, but slow. The violet tone of the faint impression takes a yellow-brown colour, and the development is finished in from ten to fifteen minutes. The prints are washed for a short time in water to free them from any adherent developing solution, and are then transferred to the toning and fixing bath.

The formula for the latter is the same as that recommended by Lumière for his "Papier au citrate d'argent," and consists of—

Water	500 parts.
Hyposulphite of soda	200 ,,
Sulphocyanide of ammonium	25 ,,
Alum	30 ,,
Solution of acetate of lead (1 : 10)	40 ,,

This mixture is warmed on a water or sand bath to about 140° Fahr., when the sediment will very quickly settle. It is then filtered, and one hundred parts of it are mixed with fifty parts of water and ten parts of a one per cent. solution of chloride of gold. The prints take in this solution first a yellow colour, and go then over to a reddish brown, and at last take a beautiful, deep, purple tone.

Toning and fixing are finished in about ten minutes. The prints are then washed in running water, and will, after drying, show no change of tone. If, in the foregoing formula, "brenccatechin" is substituted for hydroquinone, there results a developer with good keeping qualities, working, however, very slowly, and giving tones of a more pronounced violet colour. Although both these developers gave very good results on most of the above-named papers, they yet do not answer for all makes. I therefore made further experiments with other developing agents, resulting in a formula suiting alike all known brands:—

Water	1000 parts.
Sulphite of soda	100 ,,
Pyrogallic acid	10 ,,
Citric acid	11 ,,

The ingredients are dissolved in their proper turn, and the resulting clear and almost colourless liquid is used without further dilution. The citric acid acts here, as in all other developers, as a restrainer, and keeps the prints clear. In most cases development is finished in a few minutes, and the well-washed prints take in the foregoing toning and fixing bath agreeably warm tones, from a rich brown to a purplish black.

The celloidin paper of Dr. Kurz is put into the developing bath without any preliminary washing. The prints will develop quickly, clear, and bright, however faint the impression may have been. The tone will change from a reddish violet to yellowish red, and then to a yellowish brown. After development, the prints are washed for some minutes, and hen put into the toning and fixing bath, where they remain until the wished-for tone is obtained.

Bühler's mignon paper, Obernetter paper, aristo paper, and Lumière's "Papier au citrate d'argent," receive before development a preliminary washing; they are then treated in the manner already described, and, the mignon paper especially, will give warm, rich tones. The latter brand, however, has to be treated with considerable care, owing to its partiality for air bubbles.

With all these papers artificial light may be used in printing, and from two to three grammes magnesium powder burnt in any suitable lamp, at a distance of forty centimetres, should prove sufficient.

The above methods are equally well suited to the production of pictures on glass and opals, which carriers are generally coated with similar emulsions for printing-out purposes.

E. Valenta.

PHOTOGRAPHY AND PHOTO-MECHANICAL PRINTING.*

Woodbury Printing.

The next process to which we would direct your attention is the one known as the Woodbury process. This was discovered, perfected, and ied ont on a large scale by Mr. W. B. Woodbury.

The principle of the process is to obtain a metal mould carrying the p cture upon it. Into this is poured a gelatinous ink made of lampblack and gelatine (the pigment that is used for the colour can, of course, be varied). This, when warm, and in a liquid state, flows into all the hollows and gradations of the mould, and a piece of perfectly smooth paper, which has been previously waterproofed with shellac, is then placed on this liquid ink, and, after the superfluous ink is squeezed ont by means of a perfectly level piece of plate glass being placed upon the top of the mould, the ink is allowed to set. The paper can then ba peeled off, and the picture will be found adhering to the paper, its effect of light and shade being caused by the different thicknesses of the gelatinous ink which has been picked out of the mould: that is, if you were to take this picture when wet, and look at it edgeways, you would find that it is in relief. Where the mould was highest, and the ink squeezed away, you would get the high lights; where deepest, or hollow, giving the deep shadows. The picture thus obtained is now put into a solution of alum, in order to render the gelatine image insoluble in water. So much for the general principle of Woodbury type. We will now show you how you can work the process yourselves.

The first thing is to obtain a relief, and to get this you dissolve about four parts of easily soluble gelatine and two parts of lump sugar in fifteen parts of warm water; into this solution about one part of bichromate of potash is added; the solution is then strained through muslin, and poured upon a waxed glass plate, which has been accurately levelled, the warm gelatine spreade itself over the plate, forming a pretty thick gelatine layer, which in the course of a few days will dry, forming a uniform sheet, or can be dried quicker by the use of a chloride of calcium oven, and the film presents this appearance when dry. You have now a film which is sensitive to light, and this is exposed under a negative in a strong light, probably requiring about two hours or so in such light as we have in the middle of the day; after the exposure the film is taken out and allowed to soak in hot water. The parts of the film which have been affected by the light are insoluble, owing to the oxidising action of the light upon the sensitised gelatine, as previously explained to you; where it has been protected by the different shades in the negative, it will be soluble and insoluble according to the amount of light which has penetrated through to it. When the washing is finished, and the film is dry, we have a film in relief similar to the one which we now hold up, and it is from this basis that all the blocks are obtained which we use in Woodbury printing. This gelatine relief is very hard, and will stand an enormous amount of pressure, being absolutely incompressible. You will see, if you look carefully at it, that it carries the picture in different gradations and thicknesses of gelatine, and, if you pass your hand over it, you will find that it is all up and down.

We now proceed to make the printing blocks. The relief is placed upon a steel bed, such as we have here, round which there are fixed projecting edges (these edges prevent the lead spreading sideways under the pressure of the hydraulic press). The relief, together with a sheet of lead about a quarter of an inch thick, is now laid upon the steel bed and put into the hydraulic press, and a pressure given to the whole ranging from 200 to 500 tons. When taken out, you find that the lead has been pressed into the relief, and carries the image upon its surface, only, of course, the exact reverse to that of the relief. Here is a block which has been pressed in this way; here is a relief from which it was taken. We will now pull a print from a similar block to this which we have already fitted up in the press, so that you may see practically how the results of this beautiful process are obtained.

There are several new developments and branches of this process, such as the stannotype and other methods; but, as they are comparatively unimportant, we will not go into this matter now. The Woodbury principle of raised relief is used by Boussod & Valladon, of Paris, for making some of their beautiful photogravure plates; but, of course, in this instance, the relief has to carry a grain, and an electrotype is made from the grained relief, which is afterwards carefully finished by hand.

Collotype.

We have now to endeavour to explain to you the working of one of the most useful processes of photo-mechanical printing, and one which, perhaps, boasts of a greater variety of names than any other modern process. It is generally known by the name of collotype; the Germans call it "Lichtdruck," the French "phototypie," the Americans "phototype," and we English have given it the titles of "photo-print," "heliotype," "autotype," "photo-phane," "photo-mezzotype," "graphotone," &c. The basis of the process is the action of light on compounds of gelatine with bichromate of potash, and in principle it is closely allied to the process we have described to you of photo-lithography, only in this case, not only lines, but all the tones of a photograph from nature can be reproduced; and, as a matter of fact, when prints produced by the collotype process are printed on glazed paper with a suitable ink, there is scarcely any perceptible difference between them and ordinary photo-

* Continued from page 234.

graphs. Of all photo-mechanical printing processes collotype is the most useful and popular; the rapidity by which the prints can be produced render them exceedingly cheap, and it is largely employed for commercial as well as artistic purposes.

We will describe the process as it is generally worked in this country, and afterwards try to show you how the plates are printed.

The basis or principle is, as we have said, the well-known action of light on bichromated gelatine, and we have already told you that if a film of gelatine and bichromate is exposed under a negative, then washed and dried, it will, when treated like a lithographic stone, absorb water where the film has been protected by the dense parts of the negative, and refuse greasy ink; whilst, in the places where light has obtained access to the plate through the clear parts of the negative, it will refuse water and take ink. A collotype plate will not only take ink where absolutely clear glass occurs in the negative, but it will take the ink in the half-tones in exact gradations corresponding to the amount of light passing through the negative. Various substances are used to support the film of gelatine during the printing, which, we may say, is precisely the same as for lithography, and, in fact, lithographic stones were used at first as a support. Copper plates also have been employed, but now we believe that sheets of plate glass, about half an inch thick and ground on the surface, are universally adopted.

PAUL L. WATERLOW.
J. D. GEDDES.

(To be continued.)

OPTICAL PROJECTION.

THOSE who had the pleasure and privilege of witnessing the demonstration at the Royal Institution, February 26, had not only a treat, but an exceptional experience. Sir David Salomons undertook the dual *rôle* of lecturer and demonstrator, and essayed what I should think was a unique undertaking, viz., to show, in the short space of one hour, projections from the ordinary optical lantern, including chemical experiments; also microscopic projections with various powers and different sub-stage condensers and accessories, the polariscope, spectrum analysis, and a new form of apparatus for projecting opaque objects on the screen.

How perfectly it was all performed can scarcely be realised by those not present, but some general description of the apparatus and points of novelty may be interesting. The light employed was an electric arc lamp, supplied from the installation fitted up at the Institution, and adapted to the lantern by means of an adjustable support for elevating or otherwise centering the light from below the lantern. The lantern body was cylindrical in shape, and so attached to the supports that it could be revolved and stopped at any desirable position. This permitted of three optical systems being alternately employed without loss of time, for spring catches denoted the position for true optical axis with the light.

The arrangement of stands for apparatus left nothing to be desired, the whole being completely under control. Switches for the current were conveniently placed, and an electrical glow lamp, supported on an adjustable stand (automatic by pulley and counterpoise weight), supplied the light necessary for reference to notes or for preparing the apparatus for the next experiment. This, in like manner, could be switched on or off, and this prevented the lecturer having to seek the assistance of the attendant for "lights up." An optical pointer of an improved form was used, fitted with a limelight from a compressed gas cylinder, and having a cut-off arrangement. This permitted a slotted aperture, in the shape of an arrow, being illuminated and projected to any portion of the screen, the stand being fitted with universal motions, a white or ghost-like arrow indicating the exact spot the lecturer desired to call attention to.

The microscope and most of the apparatus were improvements or developments of those advocated by Mr. Lewis Wright, and Sir David gave due credit to this painstaking worker. It must, however, be admitted that marvellous advances have been made on anything previously published or shown, and the convenience of the arrangements were such that every facility was afforded for showing all necessary phenomena of light.

The subject of sub-stage illumination had been exhaustively gone into, as well as correction for objectives, and it was found in practice that two condensers, and some specially good eyepieces, gave all the addition necessary to well-corrected table microscope objectives for projecting any microscopic specimens.

The lecturer had found from experience that the amplifiers are not so satisfactory as eyepieces, no matter how perfectly the objectives may be corrected with a view to projection, and thus he was able to show objects enlarged to 4500 diameters with splendid definition, by using suitable eyepieces, with the ordinary powers.

The magnification on the screen represented an enlargement equal to about twenty times that produced in the table microscope usually. This result is a great boon to microscopists who already possess a good instrument, as they will be able to adapt their objectives and eyepieces to a suitable mount for projection purposes. They will, in all probability, have to add to their eyepieces some lower powers, so as to get the necessary range of magnification (both low and high).

The microscope used the other evening was very ingeniously supported by bars and frame, having wire stays to the top of the lantern, and thus was very firm and steady. All the objectives, eyepieces, and condensers could be changed instantly. I never saw apparatus so rapidly manipulated, and at the same time so satisfactory, even to the hypercritical, if such were present. In the case of the polariscope large prisms used for polariser and convenient arrangement for illustrating the various phenomena of polarised light made this little-known subject both interesting and beautiful, and when it was demonstrated to the audience that a bi-axial crystal, on being heated to a certain degree, became a uni-axial crystal, and, on cooling again, a bi-axial (but at right angles to the original), it was felt the *pièce de résistance* had been shown.

As regards spectrum analysis, most of the well-known points were shown by interposing certain colours singly and in combination, and also that white light was made up of coloured rays, by means of a good "white light" slide. In showing the ordinary optical projection front, opportunity was afforded of seeing the chemical experiment of decomposition of water in making hydrogen and oxygen gases simultaneously, and by means of an inverting prism, placed in front of the lantern, the tubes were seen the right way up, and consequently the bubbles of gas ascending. The lecturer was also able to project photographs of the lantern and apparatus, and the electric light arrangements on the screen, as well as illustrate the many uses electricity had been applied to in his own case for domestic and useful purposes.

The new apparatus for showing opaque objects, which the lecturer called, as he explained, for the want of a better name, the "Solidoscope," is a distinct departure, and a most successful one. An oblong, rectangular box is arranged with an aperture at each end at the height of the lantern front, and arranged inside are two total reflection prisms—one to receive the light and send it down on to the object, placed on an adjustable support; and the other to reflect it on the screen, after being magnified by a small photographic lens, placed in the right position between the object and that (the second) prism. Objects such as Barton's button—a very fine specimen, by the bye—coins, and the works of a watch were most clearly shown.

All the apparatus was of the highest order; and, technically, as perfect as possible; but, from Sir David Salomons' exhaustive experiments, it is, I think, evident that it will be possible to place in the hands of science teachers, and all interested in optical projections, apparatus of a much simpler kind, capable of illustrating the phenomena of light, by practically utilising the result of his research and applying same to modifications of apparatus in existence. This, however, could not have been if so much time and money had not been spent to show what was necessary and what was possible of achievement in the way of optical projection by well-constructed apparatus. For instance, as in the case of the microscope we now know that eyepieces are the proper thing to use with *ordinary* objectives, so, in like manner, it will be found that the polariscope can be made with artificial prisms of glass or else polarisers made of bundles of glass, that will be an economical apparatus, giving very fair and practical results when provided with proper convergent systems and suitable means of parallelising the light. Prisms are always costly, especially when large, as they have to be for projection work; but surface reflectors can be obtained that for ordinary work form fairly good substitutes. This, however, only applies to the opaque apparatus and vertical attachments, &c.; for, with the erecting apparatus, a prism must be used, and for the analyser of the polariscope, also, a Nicol prism of fair size is necessary to secure satisfactory results.

G. R. BAKER.

PHOTO-MICROGRAPHS IN THE LANTERN.

[Elizabethan Photographic Society, Barnet.]

I INTEND to divide my paper into three parts, and at times I am afraid it will appear rather dry work. At first I must deal with the subject of making photo-micrographs, then I will show you on the screen some insects and parts of insects that have had their photographs taken on

purpose that you may see how they look when highly magnified, and at the close I hope to show you some natural objects by the aid of the microscope on the screen, and, should the small living things last long enough in their small glass cells, to project some of the more visible insects in water, all of which I expect are well known to you, and will need no description.

In trying to make myself clearly understood, I shall avoid all scientific terms, and as simply as possible describe my method of working. All the apparatus that is necessary is the lantern microscope and a rather long-bellows camera, and a light of some sort to illuminate the object. All the negatives of the objects that I shall show to-night have been made with the apparatus on the table, with the addition of the camera, which I did not think that it was necessary to bring.

First, we have to consider the light. This may be an oil or gas lamp, or, as I have here and use myself, a limelight, which gives a very beautiful, clear, white, evenly illuminated disc, and very easily under control; it can be cut down, moved backwards and forwards—in fact, one can do anything you like with it, care being taken that the light is not too powerful, or it will so flood the object with light that the very delicate tracery of your object will be lost. And in all your low-power work, it is well to use a moderator, in the form of a piece of coloured glass, now behind the object; but in front of the light it is necessary to place a lens, which we will call a condensing lens—that is, to collect the light from the radiant and cone it down on the object, so that all, or nearly all, the light that you have, whether it be oil or limelight, is made to pass through the diaphragm of your microscope stage on to and through the object. But before it reaches the object there is a small lens called a secondary condenser, placed in such a position of the cone of light from the condenser to carry it on and to the objective before the beam crosses. Now in this beam is placed the object to be photographed, held in its position on the stage by a pair of spring clips. Great care should be taken that the object is clearly and evenly illuminated.

We now come to the most important part of the instrument, the objective—that is, the lens that magnifies the image, which must be of different foci to suit the object. If you want to photograph a spider, you must use a long-focus lens, that is one of a low power, about three inches, so that the whole of the object comes in the field; but if you wish to photograph a very small object, such as the dust, or, properly speaking, the feathers off a butterfly's wing, such as I shall presently show you on the screen, it will be necessary to use a much higher power, so as to magnify it so much that you can very easily see the beauty of the different forms of scales. On some moths there are as many as seven distinct scales and hairs to be found on one moth. This would require a lens magnifying about 150 diameters, but the most useful one to use is the one-inch.

Having got to the magnifying lens, and chosen the object that we want to photograph, you will see that a camera of some sort is necessary, and if one wants to be able to make pictures of any objects, such as the bacteria—which are the smallest living objects at present known, and they say half a million can rest on the point of a needle—to a good fat garden spider, you must have several lenses and a camera of rather a long extension bellows, so as to give a good range of adjustment, for at times one may have to close the camera up to, say, four inches, and at another time it may want extending to nearly three feet. I have not said anything about the body-tube and eyepiece, but these can be used, and are absolutely necessary for some work when very great amplification is required, such as photographing the very minute organisms I have spoken about.

At the end of the camera, I need scarcely say, there must be a focussing screen, which is usually of very fine ground glass. Now, for micro-photographic work it is found better to have two movable screens, one of fine ground glass, to focus on and arrange the object on; then take that away, and insert a piece of plain glass, with some very fine lines ruled on it. Then, with a focussing eyepiece, one can bring up the image to a very sharp focus.

Having got so far, we have only the dark slide holding the sensitive plate, and make the exposure. A word or two on the plate here would, perhaps, not be out of place; but I must not keep you too long with dry photographic detail. For many objects the ordinary thickly coated slow plate does very well; but if the objects are stained, such as many of the sections of wood and pathological slides are, as I will show you, or have very dark, yellow parts in them, i is better to use isochromatic plates and a yellow screen—that is ,plates that have been rendered sensitive to certain colours of the spectrum and give truer rendering in monochrome. You can buy them already prepared, or you may prepare them yourself ; but, now the Ilford Plate Company have put them on the market at 1*s.* 6*d.* per dozen, it would be much cheaper to buy them.

I forgot to say somewhere in front of the light should be placed a trough containing a solution of alum to cut off the heat-rays. It does not matter where you put it; in the apparatus on the table, the alum trough is in front of the condenser, which, perhaps, is the best place and most convenient to fix. The heat that passes from the radiant through the lenses, and brought down to a point, becomes very intense, and would burn up your object. This is not so necessary if you are using a paraffin or oil lamp.

T. E. Freshwater, F.R.M.S.

EXHIBITION AT BIRMINGHAM.

The Annual Exhibition of the Birmingham Photographic Society was held in the Y.M.C.A. rooms on April 5, 6, and 7. These were well fitted for the purpose, and the fact that they had recently been supplied with the electric light proved a great convenience when studying the exhibits after sunset and in connexion with the lantern shows. The competitions were confined to members of the Society, and the various prizes offered attracted about fifty competitors, who sent in 422 exhibits. An interesting show of apparatus was made by P. Harris & Co., W. Griffiths & Co., and W. Tylar. The prize winners were G. Wilkes, who secured a medal for "instantaneous work," and a hand camera for work done with a like instrument; J. W. Moore, for landscape, *Aber Mill;* E. H. Jaques, two medals for lantern slides, the President's prize of three guineas for Warwickshire pictures, and medals for "churches" and "doorways;" W. J. Harrison, for Warwickshire buildings; T. J. Davies, "flowers," and quarter-plate views; H. W. Southall, enlargements; S. G. Mason, transparencies; W. S. Horton, Birmingham views; A. J. Leeson, *genre*, interiors, combination prints; W. Rooke, architecture; J. P. Heaton, hoar-frost; Whitworth Wallis, portraits; and E. Winn.

It should be noted that thirteen of the classes were in connexion with the Warwickshire Photo-Survey, and that, in making numerous subdivisions, the idea was to direct the attention of photographers to distinct objects of interest in which the country is rich. The exhibition of the Society of Artists was open during the same week, and many workers with the brush came to inspect the production of the camera men. We made the circuit of the room with more than one artist of repute, and their verdict was, "Very little poor work, but much that is both technically and artistically good." Mr. Seer's *genre* picture of a *Rustic Beauty* attracted universal praise; Mr. Leeson's *Chancel, Aston Church*, was a wonderfully fine interior, while the same worker's combination picture, *A Thirsty Crew* (group of children drinking), received high praise from the judge of its class (Mr. H. P. Robinson). In all the classes the Judges had power to withhold the awards if work of sufficient merit was not presented, and this power was exercised in the case of "Large Landscapes," "Groups," "Seascapes," and "Animals."

Lantern shows were given nightly by Mr. Jerome Harrison, *Rambles in Warwickshire;* Mr. B. Karleese, *Whitby and the Yorkshire Coast;* and Mr. G. A. Thomason, *The Isle of Man.* The splendid triunial employed was operated with great skill by its owner, Mr. Howard Jaques, who took advantage of the capabilities of the instrument to introduce numerous "effects."

At the Annual Dinner, held in the Colonnade Hotel on April 9, Mr. W. J. Harrison announced that the Exhibition had been a complete success, both financially and otherwise. The President (Mr. J. B. Stone) congratulated the various members—Messrs. A. R. Longmore, G. A. Thomason, E. H. Jaques, J. T. Mousley, &c.—who had done so much hard work for the Society. An event of the evening was the circulation of the massive silver loving-cup, won by the Birmingham Photographic Society at the Crystal Palace on the only two occasions when it has been offered for competition.

THE NEW ENGLISH ART CLUB.

The New English Art Club is a small society, but it has compressed within its membership much that is daring, with a great deal that is both good and bad, of latter-day art. The eighth Exhibition, which has just been opened at the Dudley Gallery, is worth the conscientious study of the thoughtful photographer, for it not only shows him not a little which he will do well to imitate, but more—much more—that he should carefully avoid. The Exhibition is, in fact, as unequal as it is unconvincing, and whether regarded from the point of view of drawing or colour contains some of the most extraordinary examples of modern painting ever brought together.

If Mr. Thomas Simpson's *Morning on the Beach* (8) has a reposeful key of colour, it has the additional fact in its favour that it is almost photographic in its fidelity to accuracy of drawing; but Mr. Paul Maitland's *Cheyne-walk West, Noon* (14), indulges in a disproportionate expanse of monotonous foreground which no photographer would dare print. The *Portrait of Master John Mackay* (24), by Mr. G. Thompson, is distinguished by an easy and natural standing pose; and Mr. James S. Hill's *Sketch from Nature* (25) is worthy of Mr. J. Gale at his best. The colouring of *Near Arundel* (26), by Mr. Davidson Knowles, has been much praised, but his clouds are never seen in nature. Mr. G. Clausen's *Spring Flowers* (31), a portrait study of a child with flowers, is a delightfully natural picture. Mr. W. H. Bell's *Hammersmith Bridge* has too much water in the foreground, and is spoilt in being bisected by the line of the towpath. Prince Pierre Troubetzkoy's *Study for a Portrait in Open Air*, a full-length picture of a lady in a wood, may claim to be lighted in a manner which we should hope would be absent from the finished work. The pose, however, is very graceful. Of *Towards the Harbour Mouth, Poole* (48), by Mr. J. Buxton Knight, and *Between the Dark and*

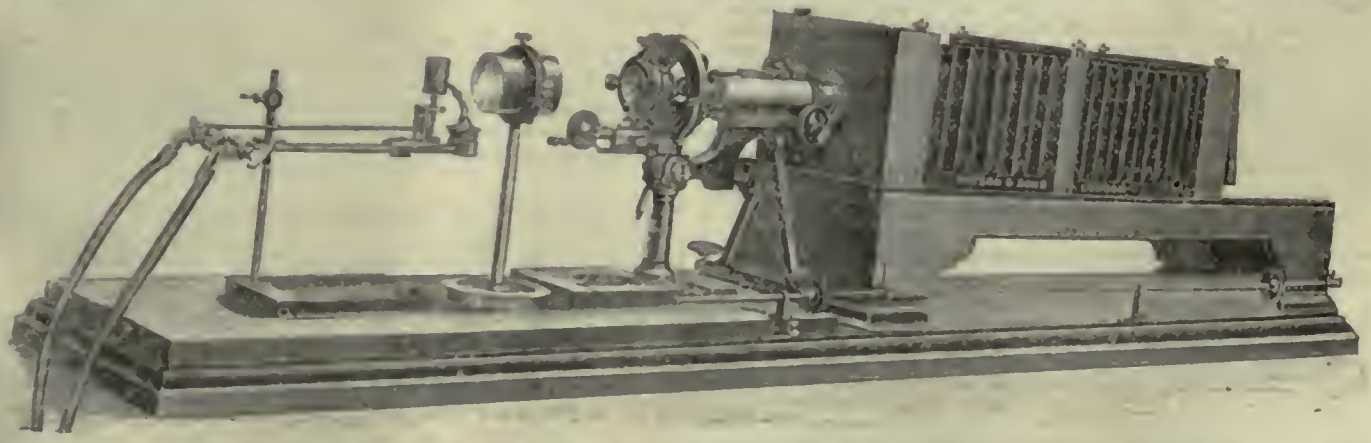
the Daylight (53), by Miss Amy Atkinson, we can say nothing higher in praise than that the subject of the one, grand as it is, is not beyond the reach of the camera, and that the other is eminently suggestive of Mr. Adam Diston's own happy mastery of dimly lighted cottage interiors. Mr. Bernhard Sickert's *Boats on the Medway—Fog Lifting* (55), has omitted the fog; and Mr. Sidney Starr's delightful *Portrait of Miss Nelly Kauffmann* suffers from a perpendicularity of the girl's arms which no photographer worthy of the name would perpetrate. As a combination of land and seascape Mr. W. J. Laidlay's *Sunset from the Cliff* is a grand piece of composition and rich colouring. Mr. C. W. Furse's *Portrait of a Lady in a Grey Dress* (67) is out of line, but the same artist's *Portrait of a Lady in a Brown Riding Habit* (73) is most elegantly posed. Mr. P. Wilson Steer's *Mrs. Albert Petre* (70) represents the unfortunate lady's face turned in one direction, and her eyes in another. Mr. George Thompson's *Portrait* (82) depicts a harshly lighted, unhappy-looking subject, and there are one or two portraits of children which, however good, technically speaking, succeed in nothing so much as arousing our commiseration for the unhappy, frightened-looking little sitters. In this connexion we select for mention Mr. F. B. Chadwick's *Study of the Baby* (92), and Mr. W. Christian Symons' *Portrait of a Boy* (102). Mr. Sidney Starr's *Portrait of Harold Frederic, Esq.* (94), is not so well lighted as Mr. Theodore Roussel's *Portrait of Bernhard Sickert, Esq.* (57)—why the "Esq.," pray?—but this is as soulless as the most over-retouched portrait that ever issued from a Regent-street studio.

It is a pity that the undoubtedly good and excellent work on the walls of this exhibition should have been set among so much which, while it is undoubtedly clever and bold, by no means merits favourable criticism because it succeeds in being unconventional. But it serves the useful purpose of a foil to the better work, while the entire collection, which only comprises about 100 pictures, and is a masterpiece of good hanging, provides an excellent opportunity of studying *fin de siècle* English art in its best (and worst) aspects.

SUMMER NOVELTIES IN APPARATUS.

A Photo-micrographic Camera.

Continuing our remarks from last week on new apparatus by Messrs. Watson & Sons, we give a drawing of a photo-micrographic camera with



a limelight attachment. This drawing shows the relative parts so clearly as to obviate the necessity for supplementing it by any description.

"Optimus" Novelties.

Messrs. Perken, Son, and Rayment have just issued a series of unobtrusive hand cameras of little bulk, covered with black morocco leather. They are at popular prices, yet no sacrifice of quality or efficiency has been made.

We give a diagram of one arranged for dark slides, and another which carries a number of plates on the magazine principle. They both have the necessary adjustment for focussing the lens.

In the magazine form the plates place themselves consecutively before the lens. Each, after exposure, is removed to the back of the others by the aid of the little bag connected with the instrument. A register indicates the number of the particular plate offered for exposure, and it is so attached to the last plate that it is quite impossible for the same plate to be twice exposed.

One ingeniously constructed view-finder is arranged so as o project either a vertical or horizontal image.

A curtain shutter is provided. It works practically without vibration, and gives exposures of varying speeds.

This little camera is rightly named "Minimus," for it is the smallest we have seen to carry a number of plates.

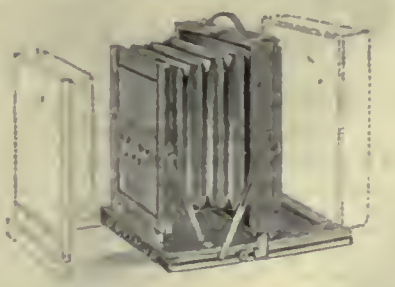
The instrument with dark slides has points of novel convenience. The dark slides instead of being inserted from the top or side are pushed

upwards from the bottom, and are, therefore, not exposed to the attacks of top light. A focussing screen is supplied which may be used when required, and provision is also made for working the camera on a tripod. A neatly arranged drop shutter, giving varied exposures, is fitted on to the front. Altogether, we regard it as a thoroughly practical machine, capable of giving the best possible results. The lenses fitted are either single view, or the "Optimus" euryscope or rectilinear, according to price.

The Cyclists' Camera turned out by this firm is admirably adapted for all who object to bulky apparatus. It is equally well suited for the lanternist, as it carries their special size of plate, viz., $3\frac{1}{4} \times 3\frac{1}{4}$. Fitted with either rapid rectilinear lens working at *f*-8, or the more rapid euryscope working at *f*-6, of $3\frac{3}{4}$ inches focus, the crisp definition obtained allows of almost indefinite enlargement. It is covered with durable black morocco, measures externally $5 \times 4\frac{1}{2} \times 4\frac{1}{2}$ inches, and must become very popular among those who appreciate *multum in parvo*.

Improved Rayment Camera.

Mr. Rayment, we think justly, claims that his present model is among the very lightest of actually rigid cameras offered to the public. It is improved up to date, now possessing a simple and instantaneous mode of attaching the lens board to or detaching it from the baseboard. The connexion, at the same time, forms a means of securing the lens board parallel with the focussing screen, or at any given angle when swinging the screen. The rapidity of opening and closing the camera is greatly facilitated by the additional arrangement for throwing the pinion out of gear with the rack. The rack and pinion are essentially necessary at the



moment of accurate focussing, but it is an immense convenience to temporarily dispense with their action when it only forms an obstruction to closing or opening the camera speedily.

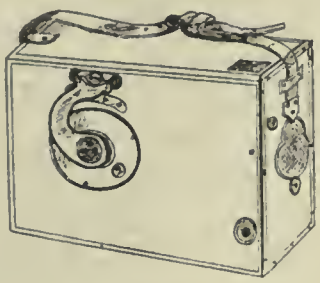
As now arranged, the focussing screen and body may be readily brought close to the front of the baseboard, so preventing a curtailment of view when lenses of short focus and wide angular aperture are in use.

All movements necessary to the modern scientific photographer are included in this compact instrument, and the workmanship is such as to well excuse the firm for adopting the trade mark "Optimus."

THE FRENA CAMERA.

London Stereoscopic Company, 106 and 108 Regent-street, W.

The camera under notice, the "Frena," bristles with new features in every available place. As will be seen from the accompanying block, externally, the camera is of the ordinary box pattern, and is covered with black morocco leather, and is remarkable for its small dimensions, especially when its carrying capacity is considered, the normal load being forty celluloid films, ¾ inch square. On opening the back of the



camera, the reservoir for unexposed films is at once visible, and to fill it it is only necessary to drop the packet of films, which, by the way, are alternated with thin opaque cards, into position. A loose back, fitted with a spring to press the films forwards, is placed behind them, and the back closed, the whole operation only occupying a few seconds. The changing is effected by pressing down the handle at the side, when a single film, with its backing card, falls into a lower chamber, where it is automatically seized and held down by a spring clip. The device for releasing the films seriatim is as original as it is effective; each film is deeply notched along two of its sides, the separating cards are also notched, but in such a way that the notches do not coincide when the pack of films and cards are in position, that is resting on a series of little metal pegs which are made to slide in the sides of the reservoir; when the handle at the side is turned, the reservoir, or film chamber, goes from a vertical to a horizontal position, at the same time the whole set of pegs moves like an escapement, and allows a film to drop, meanwhile gripping the card behind it firmly, a continuation of the same movement releases the card and grips the next film, which is then in position for exposure. It will be noticed in the illustration that the changing handle is fitted with a spirit level, this enables the turning plate chamber to be utilised as a swing-back one, moreover, of the most correct design. As it is pivoted at the centre, the photographer has only to adjust the view in the finder, and to move the spirit level till the bubble is central, and he is then assured that he is free from that bugbear of hand-camera work, "drunken" architecture. The shutter, which is constructed of two aluminium plates, is always covering the lens, a small knot serving to wind up the spring for each exposure. It is capable of adjustment for from ¼ to $\frac{1}{50}$ of a second, this being effected by varying the aperture in the revolving disc, while leaving the spring at a fixed tension. The lens is one of Messrs. Beck's Autograph Rapid Rectilinears, and works with an aperture of *f*-11 at a fixed focus, all objects beyond about thirteen feet being sharply defined. An automatic tally indicates the number of films exposed, showing a figure through an aperture below the changing handle.

Our Editorial Table.

THE "PHOTOGRAPHIC QUARTERLY" FOR APRIL.

London: HAZELL, WATSON, & VINEY.

THE articles in the current number of the *Quarterly*, though few in number, are excellently selected, and withal well written. The paper on "Warm Tones on Bromide Paper," by Mr. E. J. Wall, contains a mass of useful information on a subject of current interest. The Rev. F. C. Lambert, Rev. T. Perkins, M.A., and Mr. J. A. Hodges are among the contributors. The article on "The Photographic Work of Robert Hunt," by Mr. Andrew Lang, F.C.S., is a sympathetically written account of the achievements of one of the Dii Majores of photography.

EXPOSURE NOTES FOR USE WITH THE WATKINS EXPOSURE METER

Birmingham: R. Field & Co.

WE have received a copy of the second edition of this little work which, besides information on its own special subject, contains many items of general photographic interest.

MESSRS. TAYLOR, TAYLOR & HOBSON'S COMPETITION.

THE prize of twelve guineas which Messrs. Taylor, Taylor, & Hobson offered for the best negative taken with their lenses has been awarded to Mr. Acton T. Bucknall, of Kidderminster, for a negative entitled *Unloading*, and the second prize of six guineas to Mr. Charles C. Coulson, of Glasgow, for one entitled *In a Crofter's Cottage Home*. A special prize of one guinea was awarded to Mr. J. A. Pollock, of Belfast, for a negative entitled *In Belfast Lough*. One hundred and eighty-seven photographs were entered for competition. We have received prints from the first two negatives, the subjects of which are artistically chosen and well exposed.

CATALOGUES.

MESSRS. J. J. GRIFFIN & SONS' 1892 spring price list is not intended to be a complete catalogue of photographic goods, the firm's object being only to include particulars of such novelties in apparatus or materials as are of real practical use. In this object they have succeeded admirably.

MESSRS. HINTON'S 1892 Photographic Price List gives particulars and prices of the varied stock of apparatus and material held on sale by this firm, including its many specialities. The list is compiled with evident judgment, obsolete articles being excluded.

Mr. F. V. A. LLOYD, the successor to the late Mr. H. Newton, of 5, South John-street, Liverpool, has submitted to us his Photographic Catalogue. It seems designed to cater for the wants of the amateur, who will find all his requisites included in it.

PHOTOGRAPHIC SCRAPS for April contains a useful article on "The Choice of a Photographic Size," which should receive the attentive study of the amateur photographer. A great many practical hints as to the use and manipulation of the Ilford printing-out paper are also given, which strike us as being equally valuable for gelatino chloride surfaces generally.

THE catalogue of the Birmingham Photographic Society's recent Exhibition is enriched with some illustrations of several of the pictures shown. It forms a pleasing memento of the exhibition.

Meetings of Societies.

MEETINGS OF SOCIETIES FOR NEXT WEEK.

Date of Meeting.	Name of Society.	Place of Meeting.
April 19	North London	Wellington Hall, Islington, N.
,, 19	Oxford Photo. Society	Society's Rooms, 136, High-street.
,, 19	Southport	Shaftesbury-buildings, Eastbank-st.
,, 20	Brechin	14, St. Mary-street, Brechin.
,, 20	Bury	Temperance Hall, Bury.
,, 20	Hyde	
,, 20	Manchester Camera Club	Victoria Hotel, Manchester.
,, 20	Photographic Club	Anderton's Hotel, Fleet-street, E.C.
,, 20	Portsmouth	Y.M.C.A.-buildings, Landport.
,, 20	Southsea	
,, 20	West Surrey	St. Mark's Schools, Battersea-rise.
,, 21	Birmingham	Lecture Room, Midland Institute.
,, 21	Brixton and Clapham	Gresham Hall, Brixton.
,, 21	Camera Club	Charing-cross-road, W.C.
,, 21	Greenock (Annual)	Museum Com. Room, Kelly-street.
,, 21	London and Provincial	Champion Hotel, 15, Aldersgate-st.
,, 21	Oldham	The Lyceum, Union-st., Oldham.
,, 22	Cardiff	
,, 22	Holborn	
,, 22	Maidstone	"The Palace," Maidstone.
,, 22	Richmond	Greyhound Hotel, Richmond.
,, 22	West London	Chiswick School of Art, Chiswick.

PHOTOGRAPHIC SOCIETY OF GREAT BRITAIN.

APRIL 12.—Ordinary Meeting,—the President (Captain W. de W. Abney, R.E.) in the chair.

Lieutenant F. Davies, Major-General F. Lloyd, and Mr. H. N. Harben were elected members of the Society.

The HON. SECRETARY read a paper by Mr. W. E. Debenham on *Relative Exposures for Varying Proportions of Image in Copying*. [This will appear in full in a future number.]

Professor C. V. BOYS then gave a lecture, illustrated by lantern slides, on *Photographing Rifle Bullets*, prefacing his subject by a description of the system adopted by Lord Rayleigh in photographing soap-bubbles and drops of water by the aid of the electric spark. Upon this apparatus the Professor now indicated an improvement of his own, allowing of the bubble to break at a definite point at which it could be photographed, or as soon after as one pleased. Professor Boys said the photographing of rifle bullets was no novelty, and he described the apparatus used by two foreign photographers. In this, the bullet was photographed by means of the electric spark through lenses into a camera, but his own method did away with either camera or lenses, the shadow of the bullet cast by an electric spark being received direct on the plate. At the outset of his experiments he had to determine the lengths of the different sparks, and to ensure a small spark which, though lasting for a very short time, would give enough light. The magnesium spark was too long, although the light only lasted the one-hundred-thousandth part of a second; he thus selected copper terminals, the jar being charged by a Wimshurst machine. The bullet in its discharge struck two wires, a spark was caused between the terminals, and the bullet thus photographed on the sensitive plate. A slide of a bullet from a Martini-Henry rifle showed it to be perfectly sharp, with the waves of air; a second, of the bullet from a magazine rifle, with the new smokeless powder, travelling at the rate of 2000 feet a second, or 1600 miles an hour. In this slide the phenomena of the sound waves and waves of compression were distinctly shown, the lecturer remarking that such phenomena must have been lost by a lens. In another slide one of a series of transverse holes made in the bullet was clearly shown, thus indicating its rotational movement at a certain distance from the rifle. Bullets photographed by magnesium sparks were less clearly defined than those by the sparks from copper terminals. Waves following in the wake of bullets were depicted, and their relative velocities thus estimated. Bullets passing through glass three-sixteenths of an inch thick, produced the phenomenon of a higher density of air within a short radius of the impact due to the lead dust thrown. Bullets travelling in various directions, and numerous other phenomena of air and sound were the subjects of other slides, the lecturer remarking that the physical phenomena shown were of greater interest than the photographic.

At the conclusion of the lecture,

Mr. J. SPILLER referred to some experiments made at Woolwich Arsenal shortly after the Crimean War, in photographing the flight of a projectile from a 36-inch mortar, but the apparatus employed was not sufficiently ingenious for catching the image as it appeared—a globular mass—going through the air. He complimented Professor Boys on the remarkably successful results of his experiments; but, in those which he (Mr. Spiller) was concerned with, they had not the advantage of photographing the object in a closed box.

Answering questions from Mr. England and others, Professor BOYS said the whole of the spark used was one-eighth of an inch long. Sharp photographs of bullets could be obtained half an inch in front of the plate. The rifle bullets were fired through paper tunnels at a distance of twelve feet, the pistol shots at a distance of six feet. It was not difficult to photograph bullets at any parts of their career, but it was not worth the trouble. His object in undertaking the experiments was to provide a method which would be of some assistance to those interested in the problems.

The PRESIDENT, in moving a vote of thanks to Professor Boys, said they had the advantage of seeing the results of a series of experiments carried out with the greatest exactitude. It was a lesson for photographers to imitate; they should not rush at anything, as he was afraid they too often did, but think out their experiments, even if only on paper, and they would not find little details missing at the critical time. It had been a great treat to listen to Professor Boys, whom he (the President) considered a typical experimenter. He was glad that such work as his had been done at the Royal College of Science, South Kensington.

At the conclusion of the ordinary meeting a special general meeting was held, and a Committee appointed to consider the question of revising the rules.

LONDON AND PROVINCIAL PHOTOGRAPHIC ASSOCIATION.

APR 7.—Mr. C. H. Cooke in the chair.

Mr. C. Goodwin Norton was elected a member of the Association.

Mr. ALEXANDER MACKIE, after pointing out the beauty of the transparencies produced by its aid, and remarking that, if it was not the best method for making lantern slides, it was as good as any, gave a history of the *Collodio-bromide Process* since its publication on September 9, 1864, by Messrs. Sayce & Bolton, when it left their hands as a quite workable process. The process in vogue before them was the wet plate, the disadvantages of which led to the introduction of various dry processes, in which the sensitised plates were washed and treated with preservatives. The number of these dry processes was legion, and for the preservatives employed the kitchen was being perpetually invaded. Such films as these were very slow, indeed they could not be exposed too long. The general dream, however, was for one solution for coating the plates, and the possibility of mixing the silver nitrate with the iodised collodion to form iodide of silver in the film was attempted, but it was discovered that the silver iodide would not emulsify. Messrs. Sayce & Bolton, however, noticed that silver bromide went down in comparatively small particles, and attempted the experiment of emulsification with absolute success. The process was still very slow, and many experiments—notably those by Mr. Carey Lea—were undertaken to make it more rapid. It was not until 1874 that Bolton simplified the process by washing the emulsion in bulk. Collodio-bromide, however, never had a fair chance, as gelatine was known in 1874, and Bennett's subsequent improvements quite drove it out of the field for making negatives. They were indebted to Mr. J. Nesbitt for having reintroduced collodio-bromide for making lantern slides. In 1885 he read a paper on the subject before the Photographic Club, in which he demonstrated a simple process, and it was that process which he (Mr. Mackie) proposed to demonstrate that evening.

Coming to the practical part of his discourse, Mr. Mackie observed that for the soluble bromide Mr. Bolton recommended the double bromide of cadmium and ammonium, but he (Mr. Mackie) thought ammonium bromide the simplest and best. As to the ether and alcohol, the specific gravity of the former should be ·725, while of the new methylated spirit he had had no practical experience, although it had been tried by a good man for the purpose, and found to answer. With the silver nitrate used he had never found any fault, but the ammonium bromide did not appear to keep well, after a time parting with some of its ammonia. In this state it would not make good emulsion. He did not recommend the preparation of the pyroxyline, for even experts failed to make two batches alike; indeed, it was the one difficulty of the process. The quantity of pyroxyline employed varied, but he thought the best was that which could be used in the proportion of twelve grains to the ounce of solvents. Having bromised five ounces of collodion with sixty-three grains of ammonium bromide dissolved in a small quantity of water, to which one ounce of methylated spirit had been added, he next gradually added 100 grains of silver nitrate, also dissolved in a small quantity of water, and said the test of success of the resulting emulsion was the colour, which should be ruby red by transmitted light. The emulsion should then be kept for some hours, varying with the bromide employed—with ammonium bromide, ten or twelve hours would suffice. The next part of the process was to get rid of the ammonium nitrate. He himself washed the set emulsion for five or six hours in a pickle jar, the water from the tap running in through a bung, and out through a glass tube let into it. Having dealt with the causes of the difficulties and faults met with, such as crapiness of the film, which he attributed to unsuitable pyroxyline, and transparent spots, often due to pyro dust, Mr. Mackie said his method of cleaning the glass was to use a solution of nitric acid, wash under the tap, and dry. To keep the film on the plate, he applied French chalk, polished, and dusted, and always found the method successful. Another method, however, consisted in immersing the plates in a boiling-hot solution of gelatine, and, whilst still hot, polishing them. It seemed to be efficacious.

Mr. P. EVERITT said he had once used potassium bromide as the bromide in collodio-bromide emulsion work, and, notwithstanding that the potassium salt was insoluble in alcohol, had produced a dense and clean emulsion.

Mr. A. HADDON remarked that Mr. Mackie had said that old ammonium bromide did not produce a satisfactory emulsion on account of the liberation of ammonia. Did he think of adding ammonia to the bromide, and so neutralising? Then, in the case of the bromide being precipitated on its addition to the collodion, would not the addition of dilute alcohol to the collodion introduce sufficient water to redissolve any precipitate of ammonium bromide formed? He (Mr. Haddon), in contradistinction to Mr. Mackie, suggested amateurs should experiment in making their own pyroxyline, as they would be more likely to find out the various causes of their difficulties. The temperature at which the cotton was immersed in the acids was most important. As regards the washing, what objection was there to pouring the emulsion into a large mass of water? By that means they would get a fine state of division, and would eliminate the soluble salts much more rapidly.

Mr. MACKIE could not suggest any better way of restoring the deteriorated ammonium bromide than by fuming with ammonia. As regards the method of washing mentioned by Mr. Haddon, it had been suggested years ago by M. Chardon. Bolton and others had said that precipitated emulsions would not keep.

Mr. J. D. ENGLAND said he had tried Colonel Waterhouse's formula with ammonio-nitrate of silver, acetic acid being added to obviate free ammonia, and found it gave good results. He had found an emulsion washed according to Chardon's method keep good for a month.

In reply to a question of Mr. Archer Clarke,

Mr. MACKIE said he did not pour back the surplus emulsion into the same bottle, as a certain quantity of the solvents would, of course, be evaporated. He preferred to thin down the surplus and filter it again.

Mr. W. E. DEBENHAM, after bearing testimony to the utility of Mr. Mackie's demonstration, said he himself used ether at ·717, as it was desirable to have it pretty strong. He thought crapiness due to the water, which had been insufficiently removed from the emulsion. He had dried the pellicle between sheets of blotting-paper in a box which was placed on an oven.

The CHAIRMAN said he had quickly dried pellicle by placing it on a sheet of glass in a box with chloride of calcium.

Mr. DEBENHAM (continuing) said that Mr. Mackie had stated that the rubber edging did not show where the collodion came over it, but he (Mr. Debenham) found it did, and would therefore keep it within very narrow limits. As to the employment of French chalk, many did not succeed on account of the wrong directions given for its use. A little should be used, and rubbed very hard on the glass; if not rubbed on hard, it would not adhere. He had some emulsion, made five years ago, which he had found five or six times as rapid as emulsions made and used at once.

The CHAIRMAN said he was surprised to hear Mr. Mackie say that he had not found drying marks show after development. He (the Chairman) generally found that they did.

After considerable further discussion, Mr. Mackie was thanked for his demonstration, and the meeting closed.

North London Photographic Society.—April 5, Mr. J. Douglas in the chair.—Mr. A. L. Spiller was elected a member. Specimens of a new rubber cloth for focussing cloths and camera wraps, made by the London Rubber

Company of Liverpool, and of Mr. Otto Scholzig's new collodion paper were passed round for examination and experiment. Dr. Jeserich's paper on *Photography as Applied to the Detection of Crime*, lent by the Photographic Society of Great Britain under the new affiliation arrangements, was read by the Secretary, the lantern slide illustrations being shown by Mr. B. J. Grover. The paper is now appearing in the *Journal of the Photographic Society of Great Britain*, and will, no doubt, be fully noticed in the ordinary way. There will be no meeting of this Society on Easter Tuesday evening, the next meeting being a special Lantern Evening on Tuesday, May 5, when members will have the opportunity of introducing ladies.

North Middlesex Photographic Society.—April 11.—Lieutenant-Colonel J. GALE delivered an address, entitled *Rambles, Rural and Pastoral*, illustrated by lantern slides, to an audience of about 150 of the members and their friends. The slides were divided into sections, according as the predominating interest was purely of a landscape character or depended upon figure subjects. It is needless to say that the slides were marked by a perfection of *technique*. The audience was alternately struck by the boldness and originality of design shown in some of the slides, and the delicate treatment of atmospheric effect in others. The apparent absence of self-consciousness in the models employed was a tribute to the skill of the master-mind who posed them; and the artist's patient watchfulness and sympathetic love for the fleeting and varying moods of nature was marked by the successful manner in which he had obtained effects which, to the ordinary worker, seemed incapable of realisation. Amongst others may be noted one where the effect of a belt of clouds throwing its shadow across a broad down had been secured, when a minute's delay in making the exposure would have marred the picture. The audience marked their feelings by a vote of thanks to the lecturer, proposed in suitable terms by Mr. H. Walker. The next meeting will be held on Monday, the 25th inst. This will be a Technical Evening, and visitors will be welcome, and also at the Society's Outings, which will be held on every Saturday after Easter during the season.

Holborn Camera Club.—April 8, Mr. E. Clifton took the chair and distributed the prizes won at the Annual Exhibition in March.—Mr. Golding took a silver medal for the best picture in the Exhibition, and Mr. West was awarded a bronze medal for the next best picture. Amongst the other prizes awarded was an enlarging apparatus, a flash-lamp, a plate-washer, two clocks, two Thornton-Pickard shutters, a volume of the *Graphic*, a silver matchbox, a gold pin, &c. After these prizes had been distributed to the different winners, a gold pin was presented by the Club to Mr. Bell for the work which he had done for the Club in the office of Treasurer for the past two years. A silver matchbox was also presented to Mr. Benest, the Lanternist for the past two years. Some excellent songs were afterwards given by various members and friends. On Saturday the first official outing of the year was attended with splendid weather. Hampstead Heath was the rendezvous, and some excellent work was done.

Kensington and Bayswater Photographic Society.—April 11, Mr. Sydney C. Mote presided.—A question was read from the question-box, namely, "What is the best method of ascertaining when development of a negative is complete?" Mr. J. D. ENGLAND gave a paper and demonstration on *Celluloid Films*, illustrating his remarks by handing round sheets of the different kinds of celluloid, and by developing some films before the audience. He gave a history of the use of celluloid, stating that it is prepared by the treatment of paper pulp by nitric acid, and, after being well washed, is combined with camphor, cut into sheets of varying thickness, and hung up to dry for a time, often extending to three months. They are afterwards rolled, to give them the required surface. The advantages of celluloid films are their lightness, and consequent portability, as compared with glass, and their comparative freedom from halation. The difficulty of keeping them flat during exposure may be overcome by the use of "film-carriers," which are pieces of cardboard having a thin strip of metal at two or three of their edges. In developing, it is best not to wet the film previous to insertion in the developing solution, but to have a small quantity of water at the bottom of the developing dish, which will cause the film to lie flat, and the developer may then be poured upon it. The varnishes which may be used for preserving the negative on a celluloid film are, first, amber, dissolved in chloroform; second, gold-size, thinned with benzol; and, third, a water varnish, made by dissolving shellac in an aqueous solution of borax. The first two should be applied by means of a soft brush, and the film should be dipped into the last (while wet from the washing), and hung up to dry in the usual way. Mr. England also showed some lantern-slide carriers for celluloid films, invented by Mr. Scanlan. He stated that, by using these carriers, the films were protected from the great heat during the time the slides were being shown upon the screen.

West London Photographic Society.—April 8, the President in the chair, Lantern Evening.—Slides exhibited by Messrs. Stein, Lamley, Grindle, L. Selby, Scantlebury, Hodges, Dixon, Bilton, H. Selby, Rogers. The Annual Dinner will be held on May 13.

South London Photographic Society.—April 4, Annual Meeting.—The officers presented their annual report, which showed the Society to be in a flourishing condition, and that several steps had been taken to increase its usefulness. The work shown at the last annual exhibition was a much higher standard than previously. The programme and list of excursions for the summer session promise to be very attractive. The officers for the ensuing year are as follows:—*President:* Mr. F. W. Edwards.—*Vice-Presidents:* Messrs. Banks, Howell, Munyard, and Rice.—*Committee:* Messrs. Boxall, Eldridge, Fellows, Fitness, Groves, Herbert, Lyon, Miller, and Webb.—*Curator:* Mr. Moss.—*Hon. Secretary:* Mr. C. H. Oakden, 51, Melbourne-grove, East Dulwich, S.E.—*Excursion Secretary:* Mr. W. F. Slater, 169, Sonthampton-street, Camberwell, S.E.

Brixton and Clapham Camera Club.—April 5.—An entertainment was provided for the members and a number of friends, the items being a set of slides by Mr. B. G. Wilkinson, jun., and a set by Mr. Charles Whiting, of the West London Society. These latter comprised an excellent series of Canterbury and Stratford-on-Avon. Mr. Wilkinson's slides were mostly of landscape, with figures, many of them being well know, and tended to shown the pictorial capacities of our art. Mr. W. H. Harrison was elected a Vice-President of the Club.

Richmond Camera Club.—April 8, Mr. Cembrano presided.—A representative of Messrs. James Braine & Sons showed and explained their "Book" Camera, and the "Modern" Camera. Mr. Davis read a paper on *Pictorial Composition*, touching upon some of the principal rules applicable to landscape work.

Croydon Microscopical and Natural History Club (Photographic Section).—April 8, Mr. H. C. Collyer in the chair.—Mr. J. W. SMITH demonstrated an improved platinotype paper that has recently been brought out by Mr. Willis, of the Platinotype Company. Mr. Smith described the working of the new paper, the advantages it practically has over the old hot-bath process, and the liberties that can be taken both as regards exposure and the after-developing. Mr. Smith developed a great number of prints in a cold bath, and, by the apparent ease and uniformity of working, all praise must be bestowed upon the new paper, the results appearing perfect. Mr. Smith then showed and demonstrated an oxyhydrogen-magnesium lamp, whereby platinotype prints may be made by artificial light, the magnesium being burnt in the mixed gases giving off a very bright light, thirty seconds being sufficient for a negative of ordinary density. The light has also the power of toning ordinary albumenised paper so perceptibly as to be of little use afterwards.

Brighton Natural History Society (Photographic Section).—This new organization is, practically speaking, the Photographic Society of Brighton All the prominent members of the late Society have enrolled themselves as supporters of this Section. A representative Committee has been elected, consisting of the following gentlemen:—Messrs. D. E. Caush, L.D.S. (Chairman), A. H. C. Corder, J. Hunter Graham, G. Foxall, W. Mitchell, J. P. S. Slinsly-Roberts, and Walter Harrison (Hon. Secretary). On Friday there was a good attendance, to listen to the Chairman's inaugural address. After referring to the dissolution of the Photographic Society, he congratulated the Natural History Society in having added to its membership so many leading gentlemen that had lately joined; the Photographic Section is a movement which had not been of hasty formation, as the scheme had been before the Council for a long time. He thanked them for the honour that had been conferred upon him, and would do his best to help forward the object they all had in view. He then proceeded to discuss in a very able manner the isochromatic plate and film questions, and he had come to the conclusion, after practical experience, that in many classes of work the isochromatic was of immense value. The discourse was profusely illustrated by means of negatives, prints, and lantern slides (shown by means of the Society's new electric lantern). Messrs. England, Edwards, Fitch, and Hardcastle lent various articles to make the subject practical. Dr. Rean (President of the Society) presented some beautiful interior prints on behalf of Mr. John Parnell, of Clapton. He also showed some paper negatives about thirty-five years old, and gave some silver prints to the Section over forty years of age. On Easter Monday the members purpose spending the day at Arundel.

Lewes Photographic Society.—Messrs. A. H. C. Corder and A. H. Webling gave a lantern entertainment descriptive of *A Holiday Tour in North Wales*. Several ladies were also present. The slides were almost entirely the original work of these gentlemen, and were of remarkable beauty, both as regards choice of subject and excellence of work. The "tour" started at the fine old city of Chester, some admirable views of the ancient towers, city walls, and the cathedral being shown. The trip up the river Dee was next graphically described, and a charming view of Ecclesdon Church thrown on the screen. The journey was continued through the beautiful Vale of Llangollen, of which several exquisite pictures of the canal and its numerous bridges were exhibited. Bettwys-y-Coed was the next centre of operations, a series of pictures from this lovely spot up the river Llugwy, as far as Capel Curig, and views of Snowdon being passed through the lantern. An excursion was then made in the opposite direction, up the river Conway, the Fairy Glen, and some of the wild and picturesque ravines on the river Lleder. The tour ceased at the historic town of Conway, its fine old castle and other interesting scenes being thrown on the screen. A most interesting and up-to-date series of views were next given of the wreck of the *Eider*, after which a set of coloured views, by Messrs. G. W. Wilson & Co., of Aberdeen, illustrating the cathedrals of England and Wales, were exhibited. The result of the Quarterly Competition was made known at this meeting. The certificate was offered for the best photograph of "leafless tree or trees." Mr. Andrew Pringle judged the work sent in, and awarded the prize to Mr. H. B. Constable, who sent in two subjects, which were placed first and second. At the June meeting Mr. E. J. Bedford will speak of *Perspective as applied to Photography: The Use and Abuse of Wide-Angle Lenses*.

Rotherham Photographic Society.—April 5, was more than ordinarily interesting. Dr. Baldwin (President) occupied the chair.—Mr. J. LEADBEATER, the Treasurer, gave an explanation and demonstration of the wet-plate or collodion process. He remarked that, as an amateur of thirty-five years' standing, he often looked back regretfully to the infancy of his acquaintance with the art of photography, when it was surrounded by a mysterious halo of wonder and expectation. The process was still thought by many photographers to give better results than any other method, and to his mind there was a brilliancy and transparency in collodion plates not to be found in gelatine plates. On this account it was largely used in making lantern slides. It had its disadvantages, however, which had led to its general abandonment for landscape work, the chief being the coating, sensitising, and developing of the plates in the field, an operation which necessitated the carrying about of a large tent, chemicals, bath, water, &c. Allusion was made to the numerous ingenious methods adopted to preserve the plate after sensitising, and some amusing ex-

periences given of the exposures which were necessary. The other business included the distribution of samples of Jacoby's collodion paper, and of several trade catalogues. *Hand Cameras* is the subject for the next meeting.

Sheffield Photographic Society.—April 5, Mr. B. J. Taylor in the chair.—Mr. T. G. Hibbert introduced Messrs. G. Houghton & Son's Shuttle hand camera, for which are claimed several advantages over all existing cameras, after which Mr. G. BROMLEY gave the second half of his subject, *Stereoscope Pictures*, in a lucid manner, which caused a great amount of practical discussion, and elicited a deal of useful information for the worker in stereoscopic slides.

Edinburgh Photographic Society.—April 6, the President (Mr. Hippolyte J. Blanc, A.R.S.A.) occupied the chair.—A paper was read by Mr. SYDNEY KEITH, entitled *A Holiday in Yorkshire*, in which he described his rambles, and showed a number of slides from the negatives he had secured. They were of fine quality, and much admired. Thereafter four new members were balloted for and admitted. In consequence of the increasing number of lantern slides, and the interest displayed in their production, it was resolved that the Council make arrangements for a special lantern section to take charge of their exhibition from time to time, and to form and establish a loan and exchange collection, and also to draw up a set of bye-laws for the regulation of this department of the Society's business. The President, in drawing attention to the forthcoming annual meeting of the Photographic Convention, which is to be held in Edinburgh in the week commencing July 11 next, said they would be glad to hear that all the necessary arrangements were progressing favourably, and that its members, coming from all parts of the country, might depend upon receiving a right hearty welcome to the city, and that the Society would do their utmost to make the occasion a cheerful and memorable, as well as a progressive, one. The presentation print for the year—which had again been reproduced by Mr. Balmain, with his usual skill and kindness—was then distributed to those present. It is entitled *Idle Moments*, and is a fine specimen of photogravure. The President (Mr. Blanc), before the close of the proceedings, was congratulated on the honour which had been conferred upon him by the Royal Scottish Academy in appointing him one out of the large list of seventy nominated for the dignity of Associate of that body.

Glasgow Photographic Association.—April 7, Mr. William Lang, jun., F.C.S., presiding in the chair.—Two new members were elected. The discussion on Mr. J. C. Annan's paper, which was continued from last meeting, was concluded, and afterwards a paper was read by Mr. LANG on *Robert Hunt and his Photographic Work*. Prints from negatives taken with Dallmeyer's tele-photo lens were the subject of much interest.

Photographic Society of Japan.—February 29, Mr. Kajima Sebi in the chair.—The following gentlemen were unanimously elected members of the Society:—Count Toda, Viscount Sagara, Messrs. A. D. Charlton, A. Rogers, F. W. Gotch, Y. Takayasu, and I. Tanabe. After this there was a Lantern Meeting, a large number of slides from work done by members during the past year being shown by a limelight lantern. The slides were all good, the large collection of the Chairman's itself, which was of the highest quality, being enough to have made an excellent show. There was a fair attendance, and all who were present showed great appreciation of the exhibition. Indeed, it was declared the best thing of the kind that had been seen by any person in this country. Mr. EDMOND R. HOLMES expressed the opinion that such an exhibition would draw a large audience in Yokohama, and suggested that it be repeated there. The proposition was received with satisfaction, and the Committee promised to make arrangements accordingly. By an unfortunate mistake, a set of slides, that it was thought would be particularly interesting—a set of Korean views by Mr. T. Hayashi, of the Japanese Legation in that country—arrived too late to be shown. These, however, and a number of other additional interesting slides will be available for the Yokohama Exhibition, the date of which will be duly announced in these columns.

Correspondence.

☞ *Correspondents should never write on both sides of the paper.*

STEREOSCOPIC PHOTOGRAPHY.

To the EDITOR.

SIR,—I have read Mr. Chadwick's criticism of my paper in your columns. I endeavoured to show that stereoscopic photographs have no value from an artistic standpoint. Mr. Chadwick says he considers poetry and art in photographs nonsense, and then endeavours to prove that these are possible even in stereoscopic photographs. His great argument, which he thinks incontrovertible, is that they find favour with most of his friends and the public generally at present. If this is to be the final court of appeal, I give in at once.—I am, yours, &c.,

Fine Art Galleries, 153, Sauchiehall-street, J. CRAIG ANNAN.
Glasgow, April 11, 1892.

DEVELOPMENT SHOWN ON THE SCREEN.

To the EDITOR.

SIR,—I see a paragraph on the above in the JOURNAL referred to as if something new. I did this experiment in our village school, seven or eight years ago, to a public audience, and several times since in private.

I proceed as follows: I have ready-exposed a gelatino-chloride plate. Into an ordinary alum trough I pour the ferrous oxalate solution, and place the exposed plate in it, film-side to the light. The plate is held by a short wooden wedge against the side of the trough, so that the developing solution is between the light and the film.

When development is complete, pour off the developer and replace with hypo.

The lantern should be placed so that the picture is not more than three feet long, as the developer cuts off a lot of the light. A portrait with great contrast from a hand negative is most effective.—I am, yours, &c., H. G. M. CONYBEARE.

The Hut, Ingatestone, April 11, 1892.

MODIFYING LENSES.

To the EDITOR.

SIR,—In the JOURNAL of March 18, in the article entitled "Elementary Notes on Photographic Lenses," the formula given for finding the focus of the lenses when combined was $\frac{A+B}{A+B-C}$, A and B representing the length of focus of each lens respectively, and C the distance apart in the mount. If this is correct, the focus cannot be more than one and a fraction. Should not the formula read $\frac{A \times B}{A+B-C}$? I have always understood it to do so.—I am, yours, &c., GEORGE C. PILE.

April, 1892.

"PHOTOGRAPHIC PORTRAITS."

To the EDITOR.

SIR,—While I agree with your correspondent, Mr. A. Maskell, that the attack in your optical contemporary upon him and his friends is both virulent and intemperate, I should like to point out that, regrettable as it may be, it is an ultimate and inevitable form of rejoinder to the heap of ridicule which the school of Fuzzitypists has, I think, with undue haste, sought to cast at the old style of photography. It is to the interest of the paper named and those associated with it to maintain that old style. Mr. Maskell and his friends have, for years past, not only assailed the artistic attributes of that style, but now they are running dangerously near to telling the world that the highly finished tools of the optician are of no further use to the modern impressionistic photographer, and what is more, they are proving the faith within them by making pictures which, while they make the judicious among opticians grieve, also provokes their trade organ to take refuge in personalities in defence of its supporters. For, did not Mr. Maskell himself show us last year what could be done with a spectacle lens (and a pretty picture it was), and cannot he now discover one of the causes of the denunciation he and his friends have been subjected to?

For the photographers of the old school, however, who think—and rightly think—that a photographic objective is a necessary adjunct to successful and discriminating landscape photography there is one consolation in the knowledge that, if a lens is of no importance in taking pictures of the new kind, the need as well as the possession of brains is about on the same plane, and thus "no lens," "no brains" will be the mark by which the new school can in future be distinguished.—I am, yours, &c.,

April 12, 1892. CHANCE BROWN, JUN.

CAN PRINTING-OUT CHLORIDE PAPER BE DEVELOPED?

To the EDITOR.

SIR,—I think it would be of advantage if the new emulsion papers which I, among many others, am using could be developed as well as printed out. Are they sensitive enough to receive a latent impression with an exposure of a few minutes to daylight? If so, it would be an advantage to be able to take a number of prints quickly at will in the daytime and develop at night.—I am, yours, &c.,

Hammersmith, April 11, 1892. COLLODIO CHLORIDE.

[See leader on the subject in another part of the JOURNAL.—ED.]

Exchange Column.

*** *No charge is made for inserting Exchanges of Apparatus in this column; but none will be inserted unless the article wanted is definitely stated. Those who specify their requirements as "anything useful" will therefore understand the reason of their non-appearance.*

Backgrounds, one exterior and one interior, good as new, for exchange for two others, must be size 8×7.—Address, T. HAYWARD, Devizes.

Splendid oil painting, seascape, 24×12, worth 3*l.* when framed; exchange for good 12×10 camera or studio accessories.—Address, WILLIAM HARE, Photographer, Sutton, Surrey.

Large washing tank, with pipe and tap, in good condition; will exchange for studio accessories. Also, splendid whole-plate shepherd portrait lens; will exchange cabinet.—Address, S. J. GANNON, Chelmsford.

I will exchange a 12×10 camera and single slide, by Ottewill, and tripod, for a modern half-plate camera with three double slides and tripod; also two interior backgrounds and Tylar's print washer, for exterior or clouded backgrounds.—Address, FRED. C. D. HURD, Shepton Mallet.

Answers to Correspondents.

All matters for the text portion of this JOURNAL, *including queries for "Answers" and "Exchanges," must be addressed to "*THE EDITOR," *2, York-street, Covent Garden, London. Inattention to this ensures delay. No notice taken of communications unless name and address of writer are given.*

**** Communications relating to Advertisements and general business affairs must be addressed to "*HENRY GREENWOOD & Co.," *2, York-street, Covent Garden, London.*

PHOTOGRAPHS REGISTERED:

F. Hoare, Cirencester.—*Collection of Foreign and Ancient Silver Plate in the South Kensington Museum.*

L. SEAL.—All nitrates are easily soluble in water.

RUETAMA.—Clearly, if the price of metallic silver recedes, the cost of its salts are also reduced.

VOLUME.—By quantitative analysis, which you will find explained in manuals devoted to the subject.

ZINCO.—The blocks are usually cut to size with a circular saw, and the edges bevelled with a metal plane.

FLASHLIGHT.—Aluminium was meant. We have not yet heard of any experiments with it in this country.

E. DOYLE.—We have forwarded the letter. Any firm undertaking the silvering of glass will execute such a commission.

E. C. E.—The matter was well ventilated in our columns last year; besides, the purpose of your letter is not clear.

TRAWLER.—The spots are apparently due to particles of some pernicious matter coming in contact with the prints while they were, presumably, in a moist condition.

E. J. LESTER.—Mr. J. Barker's formula for gelatino-chloride, for printing out, given at p. 786 of THE BRITISH JOURNAL PHOTOGRAPHIC ALMANAC for 1892, is what you require.

W. GASKELL.—In all probability a kallitype print is as liable to be affected by a mount containing hypo, or other injurious substances, as an ordinary silver print, particularly in the moist state.

C. BOYD.—The platinotype prints forwarded have been made on paper that has become more or less damp by exposure to moisture. There is no way of improving the prints now.

R. A. B. asks if paste made with pure rice flour would be better than the best starch for mounting photographs with.—If the starch be good, there would be no advantage gained by using the rice paste; indeed, it might be the other way about.

DUDLEY TOWERS.—We do not think your neighbours can interfere with the glass-house; but, as it does not conform to the conditions of the Building Act, the District Surveyor has the power to order its removal. Better with dark-blue and light-green blinds.

TONES.—The reason for your failure to "successfully employ the solution recommended by Mr. Haddon for reducing purposes" is apparent from the particulars contained in your letter. You have been using potassium ferrocyanide instead of the ferricyanide.

F. (Cape Town).—If mounts printed with a bronze powder that causes spots on the prints be used, and the mounting be done with decomposed starch paste, the effect shown on the enclosed print is fully accounted for. Of course, we cannot say in what state the mountant was at the time it was used.

PLUMBER.—Brush over the zinc with a solution of one part each of chloride of copper, nitrate of copper, and chloride of ammonium in sixty-four parts of water, and add to the mixture one part of hydrochloric acid. Allow to stand for a day after this application. Paint applied to this surface will adhere tenaciously.

PALGRAVE.—The formula for transfer ink referred to is that, we believe used, at the Ordnance Survey Office. But we advise you to purchase the photo transfer ink supplied by the dealers, instead of attempting to compound it for yourself. The operations are troublesome, messy, and not always successful in the hands of a novice.

N. BEDWELL.—The quickest way to dry a gelatine negative is to immerse it for a few minutes in two or three changes of strong methylated spirit. Then it may be dried before the fire, or in the sun. A collodion negative, whether bath or emulsion, can be dried at once before the fire immediately it is washed. Heat does not affect the collodion as it does gelatine.

C. E. W.—Supposing you were the first to register a photograph of the boat race, you cannot prevent any one from publishing any photograph they may have taken whether before or after yours was exposed. Your smart work is so much labour lost. All you have secured is the copyright in your own picture. Surely you did not expect to secure any copyright in the boat race?

SEPTIMUS.—As your experience with the lantern extends only to the use of an oil lamp, we should not recommend you to commence the limelight with a mixed jet. A "blow-through" is much safer in the hands of a beginner, and such a jet will yield a light that is ample for a private room, while, at the same time, it is quite enough for enlarging on bromide paper with a brief exposure.

G. VOSS wishes to know where thin rolled zinc is to be obtained, such as that employed for the tympans of lithographic presses when they are used for photo-lithography. Both zinc and brass tympans are supplied by all who supply lithographic presses and materials. The zinc may also be had from all dealers in sheet zinc, and the brass from any of the rolled metal warehouses in Clerkenwell.

MCDAWBER writes:—"Can you kindly inform me where I can obtain stout unbleached sheeting, eight feet wide, for backgrounds? I have tried 'Horrocks,' of Manchester, and all drapers say they cannot obtain it. Is it specially made for the purpose? I can get the width in very thin bleached sheeting (more like a handkerchief than anything else), which is, of course, useless for the purpose. If you can inform me in your next issue, I should be very grateful. It is in every-day use in London, and no doubt you can give me an address where I can obtain it."—Perhaps some of our readers can supply the desired information.

H. E. THOMAS says he has recently bought a large rolling press, second hand, and the steel plate is very rusty from its having been kept for several years in a damp room out of use. He wants to know how he can repolish it so as to make it at bright as new?—If the plate is in the state we surmise it is, the most economical plan will be to discard it altogether, and buy a new one. To resurface the plate the usual plan is to work it first with snake stone and water, next with the stone and oil. Then, when a perfectly even surface is obtained, it is polished with a stick of charcoal and oil, and finally with an "oil rubber." To remove all traces of deep oxidation from a steel plate is a long and tedious operation.

OPTIC writes: "Would you please answer the following query in your next issue?—Can a photographer who has simply been a junior assistant in a firm that has been patronised by Royalty exhibit over his front, very prominently, 'Photographer to the Queen,' having, in very small letters, the name of the firm in whose employ he has been? What steps can be taken to get him to remove the said advertisement, which conveys a false impression?"—As the photographer has the name of the firm with whom he was with in small letters, he is within his rights; but he must not use the name in such a way as to lead people to believe that the business belongs to the firm, and this, it appears, he has not done. Unless he holds the Royal warrant, he is not entitled to style himself "Photographer to the Queen."

F. BAXTER writes: "Wishing to obtain a view of a small historical village amongst some hills in South Wales, I exposed two plates with the following results:—No. 1 plate was exposed on a level with the village, and developed all right, being a very good negative indeed. No. 2 plate was exposed from the side of a mountain 800 feet above the level of same village, and something like a quarter of a mile away. I may say the plates were from the same maker, and both exposures exactly the same, within half hours of each other, and yet the No. 2 plate was unmistakably a case of over-exposure to a great extent. Will you please venture an opinion as to the probable cause, as I fancy being in so elevated a position, and looking down upon the village, has something to do with it?"—The "probable cause" was undoubtedly over-exposure and atmospheric perspective, which would have prevented a brilliant picture being obtained even with a shorter exposure.

WE understand that several of the London photographic dealers' premises will be closed from Thursday night until Tuesday morning next.

WE are sorry to learn of the death of Mr. William Priestley, of the firm of Priestley & Sons, photographers, Egremont, Cheshire, which took place on the 8th instant.

LONDON AND PROVINCIAL PHOTOGRAPHIC ASSOCIATION.—April 21, *Photography and Crime.* Dr. Jeserich's paper, illustrated by slides, also Indian and Colonial slides. 28, *The New Platinotype Paper,* Mr. W. H. Smith.

SOUTH LONDON PHOTOGRAPHIC SOCIETY.—Fixtures for April, 1892:—April 18, Excursion to Canterbury. 20, *Demonstration of the New Cold-Bath Platinum Process,* by Mr. F. W. Edwards. 23, Outing to Dulwich village and Dulwich College.

MESSRS. L. TRAPP & Co. write: "In your issue of March 25, 1892, there is an article on the 'acid action of drawing-paper of different makes,' by Mr. W. N. Hartley, F.R.S. Kindly take note that we are the sole agents for the drawing-papers of Messrs. H. A. Schöller & Sons, of Düren, who guarantee their paper to be free from acid."

MR. M. L. ISAACS writes us that, in consequence of the dissolution between himself and his late partner, he will continue, as from the 1st of January last, to carry on the business of Joseph Levi & Co., Furnival-street, wholesale opticians and dealers in photographic apparatus and materials, at the same address, and in the same manner, as he has done for the last sixteen years, during which time he has been the sole managing partner.

PHOTOGRAPHIC SOCIETY OF GREAT BRITAIN, EXHIBITION, 1892.—The Exhibition will be inaugurated by a conversazione, open to members and their friends and exhibitors, at 8 p.m., on Saturday evening, September 24. The Exhibition will remain open daily, from Monday, September 26, until Thursday, November 10. Medals will be placed at the disposal of the Judges for artistic, scientific, and technical excellence of photographs, lantern slides, transparencies, and apparatus. Blank entry forms, and any further information respecting the Exhibition, apparatus, and lantern slides can be obtained from the Assistant Secretary, 50, Great Russell-street, London, W.C.

CONTENTS.

THE BRITISH
JOURNAL OF PHOTOGRAPHY.

No. 1668. Vol. XXXIX.—APRIL 22, 1892.

THE DEBT OF ART-PHOTOGRAPHY TO SCIENCE.

One of the papers read at the late Camera Club Conference was largely devoted to the strange contention that science was doing "serious harm to photography as a picture-producing art." In support of that contention, however, no more formidable piece of evidence was produced than that "when a student ought to be studying the construction of a picture, and developing in his soul the art of lying, he is led away by the flickering *ignis fatuus* of science, and goes mad over developers." We would not give much, either for the mental equilibrium or the chances of success of the picture-making student who, when engaged in studying the construction of a picture, cannot keep his thoughts away from such a subsidiary and relatively unimportant matter as the choice or composition of the developer he is going to employ. We prefer, however, to regard the remark, together with many more of a similar cast that followed it, as a piece of grotesque and fanciful exaggeration. Nevertheless, exaggeration or not, there underlies this and similar utterances of those to whom the picture-making possibilities of photography are all-in-all, such a state of misconception, if not ignorance, as to the extent to which art-photography is indebted to science, not merely for the means, but in some respects for the methods which it places in their hands, that, in justice to photographic science, we seize the occasion to remind our artist friends that they are in danger of belittling the depth, as well as the area, of their indebtedness.

However delightful, from an æsthetic point of view, a photograph may be, it relies for its charm and beauty, outside its selection and composition, entirely upon scientific aid. If, to take a common and obvious example, portions of the picture at its margins embrace perpendicular lines, their true perspective representation relies wholly upon the skill of the optician in providing a lens which will correctly translate those parts of the picture. Even the most advanced among the new school of photographers would hesitate, we should hope, to rate any kind of distortion in a photograph, as of little artistic account. Omitting landscapes pure and simple as being for the moment out of the question, the most beautiful interiors and those subjects having figure compositions with interiors, which are and have been so popular, would be impossible but for this property of photographic lenses. Despite the strenuous teaching and examples of the new school we have referred to, a large proportion of people of cultivated taste still find much, if not most, to admire in well-defined photographs of whatever kind which owe their dominant property in a primary degree to optical skill, a property which we have yet to learn is incompatible with the observance of the strictest art canons.

Science, indeed, has "more to do with art, except to provide materials for its use," than is allowed, because—and here we confine ourselves to photographic art alone—it is the man of science who usually first teaches the photographer what varied and pleasing effects are to be obtained from the use of the materials he provides. Was it the artist-photographer who was the first to discover the merits or adaptabilities of—let us say, for example—a printing process, such as platinum printing, to certain subjects? Assuredly not. Again, to whom are all the artist-photographers indebted for the wealth and variety of tones which may be obtained on this and similar surfaces? Clearly not to themselves. By whom has the art of developing the negative been reduced to such a degree of simplicity as well as reach of effectiveness? Not the "artists." By whom has the modern gelatine plate been perfected? Who is it that has wrought out its wonderful possibilities in rendering the fine details of a view, its delicate lights and shades, its deepest shadows, its highest brilliancies? The man of science.

It is not far short of the truth to say that the greater number of modern art-photographers have been educated up to the use of the materials which men of science have provided for them by the men of science themselves. It is the man of science, using its term in its purer, if more general, sense, to whom photographic truth or untruth is referable for distinction, a point which we are glad to see Captain Abney did not miss in his remarks at the Conference. We were also pleased to observe that he pointed out that artists' perspective had improved owing to the truth of photography, a truth which is the emanation of scientific effort.

Photography is in the position, unlike painting, that it relies very greatly upon the materials provided for its best and most delightful effects, as well as for the means and method of securing them, upon scientific aid, and we believe it will continue to be the case, while the lens, the dry plate, and the printing surface are factors in the production of photographs. In photography to-day effects are produced which were beyond reach a generation ago. Is this due to the advancement of art knowledge? Partly, if you like, but not solely; the man of science has had much, very much, to do with it. We fear that it would not be difficult for us to prove that the present rage for warm and sepia tones—which are allowed to fulfil current artistic requirements so admirably—is due to the experiments of the men of science, and not of the artists themselves. By-and-by, maybe, those tones will undergo modification, and we are sure that, if they do, science will once more lead the way.

There is, we fear, a decided tendency among art-photographers to underrate the value and importance of the tools with which they work, and, more, to overlook the fact that it is often due to the men of science that they have been taught how to use them. This is a form of ingratitude possibly arising out of the elation caused by the knowledge that as a picture

making art photography is slowly but surely edging in among her elder sisters. We sincerely hope it will not be perpetuated, and in saying so much we do not seek to undervalue the high art knowledge and instincts which fortunately prevail among so many modern photographers, be they self-styled artists or not. But "Art," it appears to us, is in danger of securing all the halfpence, while to Science are only allotted the kicks. We must change all that.

RECOVERING SILVER FROM SPOILT PLATES.

Most of us, whether amateur or professional, and especially if of an experimental turn, find ourselves, in the course of twelve months, saddled with a considerable stock of "waste glass," or, in other words, spoilt plates, or plates which, after development, are of no value as negatives. It may be in many, perhaps the majority of, cases that the glass itself is of no value for recoating, for the simple reason that we are not in the habit of making plates, and at present, so far as we are aware, there is no market for such waste, which therefore soon becomes a nuisance from the difficulty of getting rid of it.

But, at any rate, the silver contained in the films, especially if they be unfixed, has a value, and the trouble of recovering and utilising it is far less if systematically taken in hand than most photographers imagine. Of course, much will depend upon the method adopted as to whether the return is proportionate to the trouble expended; but, even without having recourse to any very special arrangements to that end, the recovery of the metal is, in a small way, decidedly remunerative.

In order to attain the most satisfactory result it will, of course, be desirable to work in a methodical or systematic way from the first. For instance, under or over-exposed or fogged plates that are clearly of no use should be washed and set aside without fixing; broken or "light-struck" plates or others that for any reason whatever are not submitted to the ordeal of development will, of course, be set aside without any further treatment, because, though the silver may be extracted from them by means of the fixing bath, the plan we are about to describe is, in our opinion, a superior one. Experimental films that have been developed and fixed and have served their purpose, or old negatives that are done with, although not so rich in silver as those that are unfixed, still contain a proportion of metal that is worth recovering, and these may therefore be included with the rest, and set aside until a convenient time arrives to treat the whole lot.

The first step is, of course, the removal of the films from the glass or other support, and here we may say that in the case of glass plates the glass itself acquires a higher value and begins to assume the character of a saleable or utilisable bye-product when it is freed from its coating of gelatine and brought to a state of tolerable cleanness. As regards celluloid and paper films, the removal of the gelatine is not so easy a matter as with glass, and it is perhaps a question whether, except in the case of perfectly soluble films, the game of recovery is worth the candle. The gelatine can scarcely be scraped off, and the only alternative, the use of boiling water or hot dilute acid, will disintegrate the paper support, reducing it to pulp, which mixes with the insoluble silver salt, and partially so also in the case of celluloid, which in any case is spoilt for future use owing to the destruction of its flatness.

The hot-water method is objectionable too, even with glass plates, on account of the quantity that has to be used. A mere soaking in warm, or even hot, water will not suffice to remove the film from a developed plate, owing to the well known "tanning" action of the developer upon the gelatine; and even those that have not been developed so frequently contain alum in some form that the gelatine is only partially softened by the hottest water. Boiling in dilute acid or alkali, or even long immersion at a normal temperature, will, of course, dissolve off the films, but the mass of liquid that then has to be manipulated renders the process an inconvenient one in the highest degree. We are therefore strongly in favour of removing the film by mechanical means, which, while just as easy, reduces the residues to a convenient and workable form.

For the purpose of cleaning off the gelatine, the plates are first of all placed to soak in cold or tepid water, heat being preferably avoided. When thoroughly soaked for, say, at least an hour or two, many makes of film, especially if developed, will strip readily in a single sheet without any further treatment; but, if the water in which they are soaked be acidified with citric acid, the stripping is reduced almost to a certainty. It then remains only to loosen the edges of the film by a rubbing or pulling motion of the finger, and the whole film will come away, leaving the glass almost clean enough to be recoated.

Where, however, this treatment does not answer, a flat board must be provided, along one edge of which is nailed a thin fillet or strip of wood against which to rest the glass; also a strip of hard wood with a sharp-planed edge to act as a scraper. The filleted board is placed in a sloping position on the sink, with the fillet end furthest away from the operator, and, one of the soaked plates being laid upon it, one or two strokes of the scraper, steadily and firmly applied, will remove the whole of the film in far less time than it takes to describe the process. A large number of plates may be treated in an hour, and the jelly collected for the next operation, which consists in eliminating the gelatine.

For this purpose there is a choice of two methods, namely, boiling either with dilute acid or alkali, either of which destroys the gelatine, both as regards its setting power and its power of holding the silver in suspension. But the result differs in the two cases; boiling with acid separates the silver in the form of unaltered haloid—whether it be bromide, chloride, or iodide—whereas the action of the alkali, in conjunction with the decomposed gelatine, reduces it to the metallic state. At first sight the latter would seem to be out-and-out the better plan to adopt, as it saves the reduction of the haloid by a separate operation; but, in practice, the trouble of freeing the precipitate of finely divided silver from the dark, dirty solution that clings to it with the greatest pertinacity robs the process of its simplicity, at any rate in inexperienced hands. Probably a purer result would be arrived at by this method than by the alternative one we shall describe, where *great* purity of the silver is desirable, but it would require the care and skill of an experienced chemist.

The acid method is therefore the one we shall recommend, and for the purpose almost any acid might be used, though in practice sulphuric or hydrochloric is much to be preferred. Such at least would be the case if the residues to be treated consisted solely of undeveloped film, in which case the whole of the silver would be in the haloid form. But with mixed residues the precipitate would consist partly of metallic silver, which, by boiling with sulphuric acid, would be liable to conversion into soluble silver sulphate, which would be lost, while in the case of hydrochloric, except by very prolonged boiling, it would be only partially converted into silver chloride.

We therefore prefer to rely upon a mixture of chromic and hydrochloric acids, which, while acting even more energetically upon the gelatine, also effectually converts the metallic silver into chloride. The solution may be formed by dissolving a quantity of potassium bichromate in water, and adding thereto hydrochloric acid. The exact strength is quite immaterial; but, as both the ingredients are cheap enough, it will save time and trouble to make it tolerably active, using about an ounce of each to a quart of water. The scraped-off films are placed in a suitable-sized porcelain basin, an earthen pipkin, or an enamelled iron saucepan, with sufficient of the acid solution to cover them, and brought rapidly to the boil, the mass being well stirred until the gelatine is quite dissolved. Probably by the time this occurs the setting power will have been destroyed, but the liquid will still retain a certain viscosity, which would prevent the ready precipitation of the silver; some time should also be allowed for the conversion of the metallic silver into chloride. The mixture will at first exhibit a dirty grey colour, varying in depth according to the proportion of developed and undeveloped bromide it contains, but as the action of the acid proceeds this will change to pure yellow. When this stage arrives remove the vessel from the fire, and when ebullition has ceased watch to see if there is a tendency on the part of the silver to settle quickly; if not, continue the boiling for a few minutes longer and repeat the test.

When the silver subsides readily, set the vessel on one side until the precipitate has settled well to the bottom, then carefully pour off the supernatant liquid and replace with fresh water, and again raise to the boiling point, stirring well. Repeat the subsidence and washing until the water comes away clear and colourless; then, in order to make doubly sure of the removal of all organic matters, boil once more with dilute hydrochloric acid (without the bichromate), and again wash the precipitate two or three times.

We have now reduced our silver to the state of mixed bromide and chloride, in which condition, however, it is of no practical utility, but requires conversion into the form of nitrate. The first step to this is to bring it to the metallic state, either by means of fusion or in the wet way by electro-chemical action. Fusion in the crucible with a suitable flux gives, of course, the purest result, but is not within the capabilities of most amateurs. The alternative method consists in covering the mass of silver haloid with water containing a little sulphuric or hydrochloric acid, and immersing a few scraps of zinc, iron, or copper, the two first being preferable, owing to the pertinacity with which the copper clings to the reduced silver. By the action of the acidulated water, the baser metal is dissolved with evolution of hydrogen, which in turn attacks the silver haloid, reducing it and forming hydrobromic and hydrochloric acids, which in turn react on a fresh portion of the zinc or iron, and so keep up a continuous action until the whole of the haloid is reduced, chloride and bromide of the baser metal then remaining in solution. Now, as both bromide and chloride of copper act powerfully on metallic silver, converting it into the corresponding haloid, it is obvious why that metal is not to be recommended for use, and possibly for the same reason zinc should be used in preference to iron.

In practice we prefer to use hydrochloric acid, as with it heat may be applied to hasten the reduction, whereas with sulphuric acid there is a danger, under such circumstances, of forming sulphate of silver. The quantity required is very small, a few drops in a quart of water will set up the action, though, of course, the greater the quantity used the greater its vigour. It is preferable to use granulated zinc—obtainable at any chemist's—as ordinary scrap zinc contains so many impurities.

As soon as the zinc is thrown on to the silver haloid, the latter begins to blacken where it is in contact with the metal, and this darkening spreads gradually until the whole mass is converted. If left quiescent, however, it would be a very long time before the action was complete, for which reason the mass should be frequently stirred, to bring fresh particles into contact with the zinc, and the action will be further hastened by the application of gentle heat. The progress of the conversion may be tested when the whole mass has assumed an apparently uniform black hue, by dissolving a small quantity of the precipitate—a few grains only—in warm dilute nitric acid, when, if no unreduced haloid remains undissolved, the process is complete. It will be some time after the apparent disappearance of unconverted haloid, however, before that result is gained.

It is highly desirable that the bromide and chloride be thoroughly converted, as, independent of the uncertainty and loss arising from only partial conversion, the presence of either of the haloids in the last operation, but especially chloride, will lead to the formation of an impure sample of silver nitrate, since they are both, to some extent, soluble in hot, strong solution of silver nitrate, and consequently form a double salt.

When the conversion is judged to be complete, separate the remaining fragments of zinc from the finely divided precipitate of silver. Here the advantage of using the granulated zinc will be appreciated, as scraps of thin sheet zinc frequently break up into minute fragments, which it is impossible to separate. Pour off the acid solution, and wash the precipitate in several changes of water, and then set it aside for some hours, or for as long a period as convenient, immersed in cold dilute sulphuric acid (one part of acid to ten of water) to dissolve any chance particles of zinc. Afterwards wash well, dry, and weigh.

To convert it into nitrate, to three parts by weight of the black powder add two of strong nitric acid and four of water, and place the containing vessel in a warm place where the fumes can escape conveniently; on the hob of the fireplace answers the purpose. When the silver is all dissolved, or the action has ceased, transfer the solution to a shallow dish or saucer, and place it in a warm situation to evaporate. A warm, not hot, oven will answer. The slower the evaporation the larger the crystals, and it should be borne in mind that in getting large crystals they may be withdrawn from the mother liquor, which will retain any excess of acid; whereas, if evaporated to dryness, the excess of acid will remain in the salt.

The silver nitrate obtained in this manner, if not analytically pure, is quite sufficiently so for all photographic purposes, and its preparation helps to rid the photographer of one of his minor troubles, the bugbear of otherwise useless waste plates.

The Chicago Exhibition.—It will be seen by the letter from Sir H. Trueman Wood, which we print elsewhere, that the effect of the Government increasing the grant for the British section at the forthcoming Chicago Exhibition enables the Commissioners to make a free offer of space to British exhibitors—a concession of which, we trust, photography and its allied interests will not fail to take the fullest possible advantage.

Silver Chloride in Vacuo.—In the discussion at the Physical Society on Mr. H. M. Elder's paper upon "A Thermo-

dynamical View of the Action of Light upon Silver Chloride," one speaker said he had been experimenting for years upon silver chloride, and he announced that he had found that no darkening whatever took place *in vacuo*. He considered oxygen necessary to the action. No doubt this was an independent discovery, but the speaker could not be very familiar with the literature of the subject, as the same fact has been published years ago.

Development Shown on the Screen.—We are pleased to have elicited the fact from a correspondent, Mr. H. G. M. Conybeare, that the experiment of exhibiting the development of a gelatine plate on the lantern screen has been demonstrated before the occasion to which we referred, a fortnight ago, as having taken place at a meeting of the Photo Club de Paris. In case any one should be inclined to repeat that experiment, the details which Mr. Conybeare has furnished will be of great interest and assistance. We note that in his experiments he employed the ferrous oxalate developer, which practically interposes a non-actinic screen between the light and the plate. When we passed our remarks on M. Molteni's experiment, we were presuming that a pyro or hydroquinone, and hence a colourless developer, was employed. Has Mr. Conybeare surmounted this difficulty?

The Life and Work of Mr. H. P. Robinson.—On Wednesday, April 13, Mr. C. W. Hastings delivered a lecture, illustrated by over eighty lantern slides, on the life and work of Mr. H. P. Robinson, in the course of which he said that, in the application of photography to art, Mr. Robinson had occupied a prominent position this last thirty years, and the products of his camera would hold their own beside the works of many painters of the present day. Without exaggeration, he might be called the uncrowned King of Photography. Mr. Robinson had always been a great exhibitor, and he (the speaker) was amused on asking, when on a visit to him, to see his medals, that about a hundred of them were brought down in a clothes-basket. A portrait of Mr. Robinson having been shown, his best-known works were passed in rapid succession on the screen. Each photograph told a story or suggested a happy thought, and the lecturer remarked that by Mr. Robinson's permission he was able to explain with respect to several combination pictures "how it was done." One picture of a seagull on the crest of a wave greatly puzzled the critics at its first appearance as to how the effect was produced. One of Mr. Robinson's finest medal pictures, *When the Day's Work is done*, had as a model an old man, who as a crossing-sweeper was formerly a familiar figure in Tunbridge Wells. Pictures depending on sky effects, landscape scenes, with figures introduced to form a story, were illustrated by examples, and a description of the *technique* given. The concluding picture, *Dawn and Sunset*, was, remarked the lecturer, one to linger over, as a high testimony to the possibilities of photography when handled by an artist.

Convention Slides.—The series of lantern slides shown at the meeting of the London and Provincial Photographic Association on April 14 are not only the work of two acknowledged masters of the beautiful art of lantern-slide making—Messrs. F. P. Cembrano, jun., and H. M. Hastings—but are also of interest from the fact that they form a record of many of the places visited during the Photographic Conventions of the United Kingdom, held respectively at Derby, Birmingham, Chester, and Bath. By the way, could not the series be completed by the addition of a selection of slides made from views taken during the gathering at Glasgow? It would be superfluous for us to deal out any praise of Messrs. Cembrano's and Hastings' slides, but we may, in addition to their pictorial and historical charm, point to them as a valuable advertisement for the Convention to be held at Edinburgh next July. We are convinced that, if photographers generally had a better idea of the opportunities for securing good pictures which these gatherings provided, in addition to more solid advantages, such as offering agreeable reunions of those who would not otherwise meet, as well as opportunities for taking part in the meetings, discussions, and other functions, the Conventions would be more largely attended than they are. Of that to be held at Edinburgh we are convinced the success is assured, inasmuch as in Mr. Cembrano the Convention has secured the services of a Secretary who is working with untiring energy. There is, perhaps, one drawback about these Convention slides, and that is their instigation of feelings of regret among those who are unable to participate in the pleasure of having visited such scenes; still, on the other hand, "'tis better to have seen the slides than never to have seen at all" the views and groups they represent.

The "Draper" Catalogue.—In a recent issue of the *Annals of the Astronomical Observatory of Harvard College* there is a full account of the "Preparation and Discussion of the Draper Catalogue," which includes a catalogue of 10,347 stars. It is pregnant with facts and information of great value to those who undertake astronomical photographic work, and contains much to interest the every-day photographer. It states that Dr. Huggins again took up the work, and, since 1879 has obtained a considerable number of photographs, "none of which, however, appear to show anything like the amount of detail now obtainable. In all these attempts the spectroscope was attached to the eye end of the telescope, so that the image of the star was formed in the slit, a cylindrical lens being interposed in order to give width to the spectrum. In the method which has been so pre-eminently successful the slit and collimator, which form an essential part of an ordinary spectroscope, was dispensed with, the rays from a star already possessing the necessary parallelism, and its image being almost a perfect slit without length. It is only necessary, therefore, to fix a prism in front of the objective of a telescope, and introduce some means of widening the spectrum, to obtain a complete stellar spectroscope. For eye observations the necessary width is obtained by the use of a cylindrical lens in conjunction with the eyepiece of the telescope. For photographic work the prisms are so arranged that the spectrum lies along a meridian, and it is then only necessary to allow the driving clock to be slightly in error to obtain a widened spectrum. The clock error must, of course, vary according to the magnitude and declination of the star. The great advantage of the slitless telescope depends upon the fact that every scrap of light passing through the object-glass is utilised; with the ordinary spectroscope it will seldom happen that all the light passes through the slit, and it is further reduced by absorption in the lenses and prisms of the spectroscope.

ON THE PRESERVATION AND DETERIORATION OF GELATINE NEGATIVES.

II.

In a previous article I referred to the appearance which the metallic silver present in the sky portion of a gelatine negative had when viewed with the aid of a microscope, and described the beautifully even manner in which this silver was incorporated with the gelatine when such was in a sound condition. No sooner, however, does decay, or some disturbing element, arise in the film than we find this beautifully even formation of metallic silver assuming quite a different appearance.

A very common form of deterioration is the formation of yellow transparent spots in the film, frequently not noticed until after the negative has been varnished and printed from, very likely in a damp atmosphere.

When such are examined under a good one-inch objective, it will at once be seen that the cause of the transparent appearance of these spots is brought about by the complete alteration of the original positions of the particles of silver. They are no longer found to be evenly deposited in the film, but are observed to have shifted into little clusters and rings. The metallic silver is still present, however, but not in the same beautifully distributed manner as formerly. A marked feature in a case of this kind is the formation of these tiny rings. It will be found, on close investigation, that the outer edge of the transparent spot is surrounded by a distinct metallic ring, and very frequently another of smaller dimensions, and somewhat deeper in the film, will be found inside the outer ring. For a long time I was puzzled to account for the formation of these spots and circles, and had an idea that they were caused by some electric action driving the metallic silver from a common centre into these rings; but one day, when minutely examining a spot of this description with the microscope, I was forcibly surprised to detect a distinctly effervescent action going on in the film, and this was evidently being brought about by the bursting of very minute globules that were being

rapidly formed. Here, then, was the solution of the difficulty. A pronounced decomposition was evidently going on in the gelatine, and the bursting of these tiny globules was driving the minute particles of silver outwards into the little rings and clusters I have referred to.

These spots are frequently met with in clusters, and they also frequently show the presence of very minute crystals after decomposition has set in, and these crystals are never visible until such has taken place.

It has been thought by some writers that these spots were caused by an imperfect fixation of the negative, but I rather think this is not the case. The evil which generally accrues from imperfect fixing is quite different, and takes the form of discoloured patches, not transparent spots, as in this case; but to this I shall allude later on.

The spots in question, I believe, are caused by an inherent disease or decay of the gelatine itself, and I am led to this belief by having clearly traced some of these spots to the surface of a gelatine plate previous to its exposure. When a plate having these spots is examined in a dark room by means of reflected light, there will be seen, on close inspection, dull matt markings on its surface. Sometimes these are very pronounced, and therefore easily noticed. At other times, when the plates have been but recently coated, they are only seen with difficulty; but, whenever they be present, depend upon it such will eventually lead into the deterioration now alluded to. Such plates may develop all right, and show no signs of these spots when looked through, but they sometimes do show when being looked down upon. When such negatives come to be printed in anything like a damp atmosphere, the flaws will soon make their presence felt in the manner described. I know of no treatment that will prevent them; it is a sort of cancer in the film.

I have referred somewhat to the deterioration arising from an imperfect fixing of the negative. Here, happily, we are not left in any doubt as to being able to distinguish such, and, of course, the cure is obvious. When a gelatine negative is imperfectly fixed, there will at first at least be no pitting of the film, and the discolouration will appear in broad, or some other distinct, form of patches, seldom or never appearing as spots; and this discolouration generally puts in an appearance promptly. Doubtless many a good negative has been spoiled by imperfect fixation, a fruitful source of which is the employment of an over-used fixing bath. All valuable negatives ought to be fixed in an absolutely new bath.

Another very annoying kind of deterioration is the surface stains, arising from the use of damp printing paper. Doubtless this form of flaw is well known to almost every worker. It is perhaps the most common of all printers' troubles. An appearance of such therefore need not be described; but, as prevention is at all times better than a cure, I would refer my readers to a certain kind of treatment which experienced workers claim to be an absolute protection against this form of deterioration.

This is the application to the film, whilst wet, of a water varnish. Such treatment was well known to many old collodion workers, and experience has shown that it is equally efficacious in the case of gelatine. Doubtless many amateurs of the present day never heard of such a thing as water varnish; and, as they are not likely to be able to buy such, perhaps I cannot do better than give them a formula for its production. It is very highly recommended by those quite competent to speak of its utility from having used it, one well-known worker (Mr. W. T. Wilkinson), whose formula I now give, asserting that he never knew of a case of silver staining when such was applied to a gelatine film.

Here is the way to make a useful quantity of this varnish. Take of shellac, in thin flakes, quarter of a pound, and water one pint. Place in a tin saucepan, or other suitable vessel, on a fire or over a gas-stove, and raise to boiling point. When this is reached, add a few drops of a hot saturated solution of borax, stirring vigorously with a glass rod until the shellac is all dissolved, which will be in a few seconds. Don't use too much borax, but add slowly, and stop short of complete solution rather than the other way. After this, filter through charcoal, and the water varnish is ready for use.

For gelatine negatives this varnish is applied after they are well washed and whilst still wet. This gives a good surface to retouch on when dried, and the film may afterwards be varnished with spirit, varnished in the usual manner. They are then said to be actually proof against such silver stains as are commonly met with. It has been claimed for this treatment that a gelatine film covered with this varnish, and dried, was placed on a shelf with a cotton-wool plug from a silver filtering funnel laid upon it; at the end of three days there were no signs of staining, although no spirit varnish had been applied.

Quite recently I had brought before my notice a case of deterioration, which is sometimes also wrongly attributed to imperfect fixation. In this case the negative, which had been varnished—and a very good sample of varnish had been used, too—appeared to present scales in the varnish, these resembling in a marked manner the appearance of the formation of crystals in the film. My friend was much concerned at this, and had quite made up his mind that this scaly appearance was caused by the negative not having received a thorough enough washing before being varnished. I told him he was not going to lose his negative just yet a while, seeing that all that was wrong was on the surface, and not in the film. The negative in question was placed into a bath of methylated spirit until all the varnish was removed. This left the film in as perfect a state as it was before being varnished.

This was clearly caused by the negative having got water thrown on its surface, and the varnish, being of a very hard kind, had really protected the film in this case. It would, therefore, appear that some kinds of varnish do really protect the films from moisture; but there are, doubtless, samples that are quite useless in this respect.

In my next, I hope to refer to deteriorations frequently met in with in negatives that have been intensified with mercury.

T. N. Armstrong.

RATIO OF GRADATION.

Since my last letter to The British Journal of Photography, I have greatly altered my opinions on several of the matters dealt with in Messrs. Hurter & Driffield's paper. I had previously felt much confidence in their "correct formula," but, having reconsidered the matter lately, I now feel considerable doubt in regard to it. That formula results from an attempt to explain the influence of exposure on a photographic plate by accounting for all the energy received. Of course, the light reflected, and that passing right through, can have no chemical action in the film; it is also shown that the light absorbed by particles of Ag Br, *after* being brought to a developable condition, has no further useful effect; and a formula is given showing what the degree of intensity is which remains, at any stage, after allowing for the light so wasted. The remainder, being what is absorbed by the still unchanged particles, is regarded by Messrs. Hurter & Driffield as all effective. The energy imparted by it is treated as being entirely utilised in attacking unchanged Ag Br, and no reference is made to the fact that a part of it will probably be lost in the form of heat, &c.; but still the argument would hold good if a *constant proportion* of the energy were so employed, not varying at any stage, until the particle attacked was fully saturated—if that is an allowable expression. Of this, however, we can have no proof. Still, if that point be granted, I think there is a further difficulty. Having found the formula showing the effective light after any exposure, Messrs. Hurter & Driffield suppose that that intensity, during an instant of time (dt), will change a certain number of particles (dx), that number being found by multiplying the formula of effective light by the factors dt and $\frac{1}{e}$, l being the amount of energy necessary to change one particle to a developable condition. Now, this would certainly be correct if the effective energy were all concentrated on the number of particles represented by dx; but, as a matter of fact, it is distributed among all the unchanged Ag Br in the film. On the other hand, all the particles contained in the film, after a period of exposure, are in a *partially* changed state—that is, all have absorbed more or less energy—so it may therefore sometimes occur that, during a part of the exposure, the number reaching the developable stage will happen to average about the same as would be the case if all the light were being used in fully changing previously unexposed material. During the earlier part of the exposure it, however, would certainly not be so.

It is from an equation depending on that doubtful value of dx that the "correct formula" is derived. By it the density which will result from any exposure is asserted to depend, always and only, on the length of development, the inertia of the emulsion, and the opacity of the undeveloped plate. The opacity is made a function, because it accounts for the light which passes right through the film, and is therefore lost; but it is not easy to see how that loss could make any difference to the smaller densities, where the changed silver is all at the top of the film. When the light has produced no change whatever in the lower layers, how could an increased quantity of Ag Br (and therefore greater opacity) underneath, have led to any difference in the developable density? The light passing out of the film has already proved too weak to make any change in the last part of the Ag Br it has passed through, and could therefore have made none in a still lower layer.

Feeling now much doubt as to the correctness of that formula, I tried to form some ideas as to what would result from considering the particles as all absorbing energy from the commencement of the exposure, and, after working the matter out a little, I was at length surprised to find that I had arrived at the *short formula* of Messrs. Hurter & Driffield. This formula had been discovered by means of experiments only, and it is therefore interesting to find a method of reasoning which appears to lead to the same result. We may consider the grains of Ag Br as quite independent of each other, all absorbing energy from the commencement of the exposure, and none reaching the developable stage, either sooner or later, in consequence of anything happening to other particles. If all were equal in sensitiveness and similarly situated, they would remain unaffected till a certain stage of the exposure, and then be all changed at the same instant, half-tones being impossible. Gradation, therefore, results from the unequal sensitiveness of the particles, and from the fact that those lying more deeply in the film receive a smaller intensity of light than those nearer the surface. Now, to find the principles resulting from this, it will be convenient to consider a simple case, and suppose a film in which the Ag Br is all of equal sensitiveness, and equally distributed through the thickness of the film. Representing the exposure by It (intensity × time) and the amount of exposure necessary to just bring the Ag Br to a developable condition by i (inertia), it is evident that the grains on the surface would be changed when $It=i$, and those in any position underneath when *they* received an equal amount of exposure. If the film were now regarded as consisting of a large number of thin equal layers, and each of these allowed $(1-a)$ of the light to pass through, the combined transparency at the nth would be, as shown by Messrs. Hurter & Driffield in the first part of their paper, $(1-a)^n$. Now, at a depth where $It(1-a)^n=i$, the Ag Br would be all changed, and also in all layers above, as each of them would have received a greater intensity of light than that, but not lower. Each layer, all being equal, would contain the same amount of silver, so that the whole amount changed would always be proportional to n. If we write ϵ^{-kn} in place of $(1-a)^n$, when $\epsilon^{-kn}=\frac{i}{It}$, n is always proportional to the amount of changed silver, and therefore answers to Messrs. Hurter & Driffield's definition of density (D). From the above equation it follows that $\epsilon^{kn}=\frac{It}{i}$, and $kn=\log_{\epsilon}\left(\frac{It}{i}\right)$. The coefficient of development—modulus to common logarithms—and $\frac{1}{k}$ may be combined in a constant, as γ, and $\log. i$, being also a constant, may be written as C. With these alterations the formula would read

$$D=\gamma\ (\log. It-C)$$

That, it will be noticed, is Messrs. Hurter & Driffield's *short formula*.

Now, as the *thickness* of the reduced silver—that is, the number of supposed layers—will always be exactly proportional to the amount of that silver, we have here exactly the conditions assumed by Messrs. Hurter & Driffield in showing that density is proportional to the logarithms of transparency. While discussing the matter recently, it never struck me that the silver might be so arranged in the *interior* of the film as to just agree with the conditions assumed, but it appears that in this case it would actually be so. Mr. Chapman Jones, in an article on intensification, some time ago expressed the opinion that the deposit varied in depth with the density, but I had previously, unjustly it appears, doubted the correctness of that view.

So far, the short formula seems altogether correct, but it has now to be considered whether it must be modified when the conditions I have stated are departed from. As regards the matter of even distribution of the grains through the thickness of the film, it is probable that in most commercial plates, as they are now usually machine-made and quickly set, there is not much inequality between the amounts of silver at different depths. When the distribution is *not* regular, the imagined layers may be considered as not necessarily of equal thickness, but always of the same transparency. Then, as we have supposed them very thin, and therefore of small opacity, I think it would follow, from the arguments given in my previous letters (supposing them correct), that in that case silver, which was producing equal opacity in layers which differed moderately in thickness, would be practically equal in amount in each of them, so that it seems unlikely that the truth of the formula would be much affected by that alteration of conditions. It must be remembered also that the silver would be reduced on development just in the position it occupied as Ag Br, so that in any case the resulting opacity in the negative would not be affected.

But a much more complicated question remains to be dealt with. The grains of Ag Br have been treated as being always of equal sensitiveness, while, as a matter of fact, they really vary greatly in that respect in all emulsions. The grains belonging to any particular grade of sensitiveness in an ordinary plate would, of course, become developable when the exposure was equal to the inertia of that grade, so that all would be reduced in each layer down to the nth when that received an exposure just equal to i, and it would follow, from the reasoning previously given, that the formula would apply to the silver of each separate degree of sensitiveness, but the constant C, being the logarithm of i, would have a different value for each. Taking two grades having logarithms of i equal to a and b respectively, their densities, after any exposure, would be $\gamma\ (\log. It-a)$ and $\gamma\ (\log. It-b)$, and the sum of the silver changed in both would be $2\gamma\left(\log. It-\frac{a+b}{2}\right)$ which, of course, is merely another form of the same formula, only the constants being changed. In the same way it may be shown that the formula would apply for any number of grades of sensitiveness, C representing the average of the logarithms of inertia of the whole. It is clear, however, that the formula, in cases of emulsions of mixed sensitiveness, can only apply while all the varieties are being acted upon, and in that fact I think we have an explanation of the periods of under-exposure and over-exposure found by Messrs. Hurter & Driffield. The action begins when the exposure first equals the inertia of the most rapid grade, and, if the plate contained no other kind, it would then proceed according to the formula; but, as exposure continues, inertias of other rapidities are reached, and continually change the value of C till that of the least sensitive is arrived at. Then the growth of density proceeds according to the formula, and the "period of correct exposure" begins. After a time the most sensitive form of Ag Br will become all changed, and after that, as grade after grade is exhausted, the densities will always be less than the formula would show, and we shall then have arrived at the stage of the period of over-exposure which continues till the action of reversal counterbalances any further increase of density due to still unchanged particles, and so the maximum of density is reached.

In the case of an emulsion containing Ag Br of varying degrees of sensitivenesss, it cannot be shown as clearly as in the simpler case that the conditions assumed by Messrs. Hurter & Driffield in showing that density equals the negative logarithms of transparency really exist; but, after carefully thinking the matter over, I have satisfied myself that that rule will still be practically correct under the altered conditions. I am, therefore, now convinced that Messrs. Hurter & Driffield have been quite right in depending on the truth of the formula D=log. O, which results from it. It has, so far, been taken for granted that the different grades of sensitiveness will always be in the same proportion to each other all through the film. Where that is not practically the case, I doubt whether the short formula, or any other, would apply; but it would probably be only in very inferior plates, if any, that that would be likely to be a doubtful matter.

If the views I have described are correct, it will appear that, in order to obtain exactly true gradations, the *ideal emulsion* should be prepared with Ag Br, in which the grains are all of equal sensitiveness. That such an emulsion would give technically perfect negatives may be shown without estimating the actual amount of Ag Br changed, for, on exposure, as I have shown, the silver would everywhere be brought into a developable condition to just that depth in the film where the varying intensities of the light acting are reduced, always, to one unit—*i.e.*, to the value of i. The transparencies of that changed silver would, in consequence, be such that, by reversing matters and passing light of uniform intensity through them, the intensities emerging would be in exactly inverse ratio to those which had produced the changed state. By developing to the proper stage, and fixing, we shall have exactly preserved those transparencies, and the result will, therefore, be a perfect negative, in which, as defined by Messrs. Hurter & Driffield, "the opacities of its gradations are proportional to the light reflected by those parts of the original which they represent." In plates prepared with such an emulsion there would be no periods of under-exposure or of over-exposure, but every gradation would be correctly rendered for all exposures, from that intensity which just equalled the inertia up to that giving the greatest density which the plates could register. Development might be made a purely mechanical operation by the method of first reducing the developable silver to the fullest possible extent, and then, after fixing, reconverting the reduced silver into Ag Br. The film would then be in exactly the same state as was that portion of it which brought all the varying intensities of the exposure to one level, and its transparencies would, therefore, all be just in inverse ratio to those intensities. The production of such an *ideal plate* is, of course, im-

possible, but by means of the "centrifugal separator" it does not appear unlikely that a near approach to it might be made.

According to the principles I have stated, it would appear that there need be no limit to the range of gradation if plates were sufficiently thickly coated, but the phenomenon of reversal, I think, fully accounts for the fact that a limit certainly exists. It would occupy too much space, however, to deal at present with that matter.

H. J. CHANNON.

TONING AND INTENSIFYING BY URANIUM SALTS.

[Society of Amateur Photographers of New York.]

THE method to colour or to intensify negatives by means of uranium salts is by no means a novelty in photography. It was practised in the earliest times of the collodion process, according to a formula by Selle, who prescribed a solution of ten grammes each of ferricyanide of potassium and uranyl nitrate in 100 c.c. of water.

After the collodion had been superseded by gelatine emulsion plates, Dr. Joseph Maria Eder revived Selle's process, modifying it to some extent, and we find it described in detail on page 82 of his book, *Modern Dry Plates*, translated by Baden-Pritchard in 1881. Soon after its publication, T. C. Roche and Charles Ehrmann exhibited uranium intensified positives and negatives before the Association of Operative Photographers of New York, and ever since gelatine positives and negatives, and later bromide prints and bromide transfers, have been toned or intensified in this manner.

Let us look superficially at the chemical process taking place when toning in this manner, with especial regard to the alleged improvement of it, and the perfect preservation of the whites in the high lights.

Uranyl salts are not precipitated by ferricyanide of potassium, the so-called red prussiate, but ferrocyanide of potassium, the yellow prussiate, does so. When ferricyanide of potassium comes into contact with the silver deposit of either negative or positive, the conditions of the two substances are changed, the ferric salt is reduced to the ferrous state, and a portion of the metallic silver is formed into ferrocyanide of silver. Then only an action of uranyl nitrate becomes possible, and in combining with the reduced, the ferrocyanide of potassium, the reddish brown precipitate we desire to obtain, the ferrocyanide of uranium, begins to form. The longer the silver deposit is subjected to the action of the solution, and the more concentrated this latter is, the more intense in colour will be the deposit.

Before reducing takes place, the not yet decomposed ferricyanide and the uranyl nitrate have ample opportunity to permeate the soft and porous gelatine film. It is one of the properties of the ferricyanide of potassium to harden or to tan gelatine; a consequence of which is that the decomposition products, as well as undecomposed portions of the salts, are closely enveloped within the film not removable by washing in pure water. The white of a positive impression remains yellow notwithstanding all means employed to prevent it.

But the prints we have seen, which were made before us, can justly boast of perfectly pure whites, without any tinge of yellow in the lights, and we are told the addition of acetic acid has wrought this wonderful and very interesting fact.

The making of uranium-toned prints with pure whites is also nothing new. It is not an American invention, as has been publicly announced, I believe; and, in fact, we find the process described in all newer handbooks of photography. A formula for it by Dr. E. Vogel appeared first in *Photographische Mittheilungen*. It is as follows:

Red prussiate solution, 2 : 100	50 c.c.
Uranyl nitrate solution, 1 : 100	50 ,,
Glacial acetic acid	12 ,,

How simple the toning is will be at once understood, and I cannot possibly imagine why so much noise has been made about it. We all know the properties of the chemicals we work with, and those that do not ought to. We knew all along of the tanning properties of ferricyanide of potassium, and those of acids to soften gelatine or destroy its viscosity, and the application of the one to counteract the other is the only thing creditable that I can see.

Photographic and photo-chemical novelties are floating in the atmosphere, as it were, waiting to be picked up by the first comer, as has been said by an old practitioner, and he is right in every sense of the word.

The method of toning and intensifying with uranyl nitrate can be very profitably employed in the making of transparencies for decorative work and for projection. An under-developed gelatine lantern slide may be intensified with it to perfection, gaining at the same time an agreeable and warmer tone. Failures in lantern-slide making are almost entirely out of the question when we press the red prussiate into our service. Under-developed slides we intensify by the method described, and over-exposed and over-developed plates, subjected to a process which I will describe on some other occasion, may be made into beautifully clear and detailed slides by applying Farmer's solution.

Let us now throw a glance at the process of intensifying negatives with uranyl nitrate, not applicable to all cases of improving feeble negatives, but eminently so to some. Under-exposed and under-developed negatives, unfit to print from on account of harshness in some, and weakness in other parts, may be made excellent printers with the uranium intensifier, as long as the negative is free from fog, and perfectly clear in the non-exposed portions of it. Of course, we must dispense in this case with the acetic acid. What is deleterious to the toning of a bromide print becomes here an important factor. The yellow tone assumed by the clear parts of the negative retards the too forcible printing of the shadows, and establishes a harmony between light and shades not attainable with mercurial intensifiers on negatives of the described character. The manipulation requires a little more than ordinary attention, but there is the one consolation, in case failures occur, that the whole uranium deposit can be removed by a weak solution of cyanide of potassium, and, after washing the plate, a new intensification be undertaken.

Uranium-intensified positives may be rendered blue by immersing the plate in a solution of ferrous sulphate, also a method of considerable age, but deserving the attention of our diligent amateurs.

CHARLES EHRMANN.

ON SOME POINTS RELATING TO DEVELOPMENT AND TO THE FORMATION OF THE LATENT IMAGE.

[Camera Club Journal.]

A VERY urgent request from the Hon. Secretary that I should contribute a paper to this Conference must serve as my excuse for bringing forward the results of some experiments that were made chiefly for my own information.

I do not propose to enter into the much-discussed question of the relation between exposure, gradation, and the method of development. Removal from Leeds to the south, and the consequent upsetting of my laboratory arrangements, has prevented me from making any strict experimental inquiry into the conclusions arrived at by Hurter & Driffield. It is to be regretted that their unfortunate use of the word density in a sense very different from that in which it is commonly used by photographers should have led to a great deal of misunderstanding. Further, I do not think it has been made sufficiently clear to the majority of photographers that the ratio of the densities, in Hurter & Driffield's sense, may remain constant, but the ratios of the opacities, which is what we have to consider for printing purposes, may vary enormously, according to the absolute values of the densities.

At present I regard the unalterability of gradation by development as not proven. It is extremely improbable that so many of the most experienced photographers would have become so strongly impressed with the idea that the gradations are to some extent modified by mode of development if the idea were entirely without foundation in fact. The matter requires further investigation. Recently (*Phot. Wochenblatt*, XVII. 305–308), R. Neuhauss has stated that he has obtained considerable variations by varying the concentration of the developer. He used a sensitometer screen with thirty squares of different degrees of opacity, and exposed plates behind it for a constant time at a constant distance from the source of light. A concentrated pyro-soda developer gave squares Nos. 1 to 6 quite opaque and not distinguishable from one another, and the opacity gradually fell off to No. 26, square No. 27 being scarcely recognisable. A precisely similar plate, developed for an hour and a half with the same developer diluted with fifty times its volume of water, gave no equal opacity in the first six squares, but No. 1 was distinguishable from No. 2, and, moreover, the last square of all, No. 30, was distinctly visible. In the second case, three squares, Nos. 28, 29, and 30, at one end of the scale, had a recognisable density, whilst in the first case they showed no visible deposit, and, on the other hand, the squares at the opposite end of the scale were less dense in the second case than in the first. This means, of course, a very considerable alteration in the relative densities, and, though the variation in the composition of the developer was greater than is usual in practice, the experiment is directly opposed to Hurter & Driffield's main conclusion. I have not yet had an opportunity of repeating the experiment, but a statement of this kind by such an experienced photographer as Neuhauss indicates that the question is still *gradations in developed positives*. An

important question of the same order is the possibility of altering, by development, the gradations of positive prints obtained on bromide paper. The experiments that I shall describe were made primarily for another purpose, but they throw some light on this question.

Paper from three different factories was exposed behind the same Warnerke sensitometer screen to a small screened gas flame of great constancy.* All the exposures were of the same duration. The paper was treated with the developer without being previously wetted, and, in order to assimilate the conditions as far as possible to those existing in actual practice, development was continued in each case until it seemed that the maximum possible amount of detail had been obtained, and the denser squares were becoming indistinguishable from one another. The results are given in tabular form. The term "gradations" is used to denote the number of squares differing in opacity, or, in other words, the range of tones. In almost all cases the first two or three squares shown were indistinguishable from one another in their degrees of blackness.

Experiment.	Oxalate Solution, 25 per cent.	Ferrous Sulphate Solution, 25 per cent.	Water.	Potassium Bromide, grains per ounce.	Ilford Slow Bromide.				Morgan & Kidd (rough surface).				Eastman.

When the same quantity of developer is used over and over again, the tendency to produce fog becomes less and less, and the gradation somewhat shorter. An increase in the proportion of oxalate distinctly increases the tendency to fog. Dilution with water has no marked influence on the gradations, but lengthens the time required for development, and gives an image with a warmer colour. Addition of bromide is very efficacious in preventing fog, but reduces the apparent sensitiveness of the paper, and shortens the gradations, its influence in this respect being more marked than the influence of dilution. The precise effect of any modification in the composition of the developer varies with the character of the paper.

The influence of bromides on development is a point of much interest, and has given rise to much discussion.

Experiments made in connexion with a standard method of development (*Phot. Journal*, April, 1890) showed that, with pyro-ammonia, proportions of ammonium bromide, varying from one and a quarter to five parts per 1000, have little effect on the time of development, and no appreciable effect on the apparent sensitiveness of the plates. The advantage of bromide lies chiefly in the prevention of chemical fog, both with ammonia and with sodium carbonate. Hurter & Driffield, in their first paper, arrived at a similar conclusion, and consider that the alkaline bromide prevents general fog by preventing the dissolution of silver bromide in the ammonia.

In order to ascertain whether ammonia solutions of the strength commonly used in developers do really dissolve an appreciable quantity of silver bromide from a gelatino-bromide plate, I broke up some plates (in the dark room) and placed the pieces in stoppered bottles containing ammonia solutions of various strengths, both with and without ammonium bromide. In 100 c.c. (A) contained 0·25 gramme of real ammonia NH_3, equivalent to about 0·75 gramme of ammonia solution 880; (B) the same with 0·25 gramme of ammonium bromide; (C) the same with 0·5 gramme of bromide; (D) 0·5 gramme of real ammonia; and (E) 1·0 gramme of real ammonia. After standing for forty-eight hours with frequent agitation, the liquid was poured off and tested for silver by addition of ammonium sulphide. A, B, and C contained no silver, D contained a mere trace, and E a distinct trace, but the quantities dissolved were so small that it is difficult to regard them as playing any important part in the production of fog. Moreover, comparatively small quantities of caustic soda will produce abundant fog, both with pyro and quinol, and there is no evidence that dilute solutions of caustic soda have any solvent action on silver bromide.

In a paper on *Chemical Changes from a Modern Point of View*, read at the Conference in 1889, I pointed out that the operation of developing must be considered from the point of view of chemical dynamics. It is well known that in many chemical changes the rate of change is affected by the quantity of the products of the change already present. Now, in alkaline development, the reduction of unexposed silver bromide by the developer would result in the formation of an alkaline bromide. If an alkaline bromide is previously added to the solution, the tendency to the formation of more bromide will be reduced, and hence the reduction of the silver bromide will be retarded, or, with a certain proportion of alkaline bromide, prevented altogether.

C. H. Bothamley, F.I.C., F.C.S.

* The standard flame that I use for exposures of this kind is extremely constant, and plates of the same kind, exposed for the same time and developed in the same way, always show the same sensitometer number.

PHOTOTYPES *VERSUS* PHOTOGRAVURES.

[Anthony's Photographic Bulletin.]

Let us first consider the ordinary half-tone photo-engraving, of which so much has lately been seen in the way of illustrations for the higher-class periodicals and works of an art and technical nature. We shall find that these prints all render the half-tone of the original, or, to be less technical, show the various degrees of light and shade, in masses of colour differing in degree, but in flat tints, produced by breaking the original subject, that may have been either a wash drawing, painting in colour, portrait from life, or view from nature, into an immense number of dots, obtained by photographing through the fine meshes of a ruled glass, in a manner not necessary of description here.

The resulting picture is transferred to the metal that is to serve as the finished plate; the chemical action is proceeded with, and the half-tone plate that results shows the picture in relief, and the entire surface of the plate, a mass of fine points, or dots, separated by fine furrows running in transverse directions, the points in relief being the printing surfaces. The plate being blocked on wood or metal to render it of the same height as type, it is inked up with a roller in the same manner that type is, and the ink, adhering to the points, is impressed into the paper that is brought in contact with them in the printing press. It should here be noted that, the points or dots making up the printing surface of the plate being all of the same height, the amount of ink deposited on the paper is of the same depth or thickness from each and every printing point, and it naturally follows that variations in the light and shade making up the picture are dependent on the number and size of such dots within a given radius; thus a heavy shadow in a picture printed from relief plate

will be seen to be composed of a large number of these dots, often so close together as to merge into one another, while the high lights are the result of a preponderance of the clear transverse lines, that serve to separate the dots more widely, only showing them sufficiently to give form and colour to their object.

The above are the principal points of identification of a print made from a half-tone type plate in relief, and are easily to be distinguished from pictures produced from intaglio plates, as will be shown further on. There is still another kind of half-tone relief, however, that is not so easily distinguished, and this is the photo-gelatine, or heliotype, and kindred processes, which, in rendering the gradations of colour, do not cut them up into dots, but lay the ink in smooth masses of different tones on the paper from a surface of gelatine. It is not the intention of this article to go into all the varying methods of printing in relief, but merely to contast as strongly as possible the wide difference between the rightful photogravure and the many cheap illustrations printed in a type press that have so frequently been foisted on an unsuspecting public under the guise of such.

The photogravure is printed from an intaglio plate, and is not capable of being used in a type press under any conditions. It can only be successfully printed by an expert, and where, with a relief plate, the office boy might "kick off" say, a 1000 a day, or the steam cylinder press 10,000, the expert printer, with his intaglio plate, would not produce above 200 good impressions. The intaglio plate is filled while warmed with a hard, stiff ink, which is pressed into every depression, and after the high lights of the plate are carefully "wiped off," by hand, the plate is run through the press, in connexion with the paper, and the latter lifts from the sunken surface of the plate all the ink it has previously received, holding it on the surface of the paper in masses of colour that differ in depth, and consequently in tone, according to the depth of intaglio in different parts of the plate, the result of which is a series of gradations from the pure high light of the clear paper, to the rich, velvety black of a solid body of ink spread over the surface of the paper and not pressed into it. The grain, too, of this plate, instead of being composed of noticeable cross hatchings of lines and dots, is a scarcely discernible "tooth," that is obtained by chemical action on the metal plate before the picture to be etched is transferred thereto. Carbon tissue, being the medium through which the transfer is made, and the finished print very closely resembling in most of its features that beautiful pigment, it is a wonder that the feeling of those interested in seeing justice done to all has not been more forcibly expressed on this subject before.

A name that would answer the purpose, and still be meritorious, is the old title photoglyph, as it applies to all plates which give reproductions from relief surfaces, while photogravure is properly used only in the opposite connexion. Let all, then, who know better be honest enough to call things what they are, and thus do what they can to avoid further complication of the already multitudinous collection of process names in existence both in this country and abroad.

PHOTOGRAPHY APPLIED TO MEDICAL RESEARCH.

[Camera Club Journal.]

In an extremely interesting, instructive, able, and pregnant address lately delivered to the Photographic Society of Great Britain, Professor Meldola touched on the various services rendered by photography to such special sciences as astronomy, spectroscopy, &c., but I was surprised and disappointed that he did not dwell more strongly than he did on the services rendered by our science to medical science. I have little hesitation in saying that the services of photography to medicine have been most important, and I have no hesitation at all in saying that the use of photography is growing in medical schools more than in any other educational and scientific establishments. I believe that before long every medical school, every hospital, will have its installation for photographic work as an essential part of its equipment.

There can be no doubt that the utility of photography in such branches of special work is vast, and, in order to make myself more clear, I propose to divide my subject into two main heads: Macroscopic or Gross Photography and Microscopic or Photomicrographic work.

Under the first head we may notice the reproduction by photography of morbid specimens removed from the living or dead body, but I do not propose to trouble you with objects which are of little interest to many, and positively distasteful to some. I may, however, use two or three slides to illustrate the use of photography in recording the course of disease. Here is a photograph of a case of ordinary "knock-knee" in a boy before operation, and the next slide shows the same leg after operation. They are not even now quite the limbs of an Adonis, but at all events the patient has, after the operation, some mobility and some use in his legs. Here is a slide showing a tongue affected with *epithelioma*, and it is evident that the patient could not have suffered his tongue to be held out in this position long enough for a sketch, however rough, to be made, while this photograph was produced in the twinkling of an eye by means of the flashlight. These three slides were made from negatives taken by Mr. G. L. Cheatle, of King's College, who, a few months ago, had no knowledge of photography. In connexion with flashlight work, I may say that this late development of photography is of the very greatest utility in ward portraiture; by means of flashlight we obtain results with much more certainty and success than we could hope for with ordinary daylight "parlour portraiture."

Now, photography of this kind has its limits and its dangers. It is limited by our limited power of reproducing colour, and where colour is an essential part of diagnosis, for instance, we find ourselves sometimes without a perfect tool if we trust to photography. In skin diseases colour is an important factor in diagnosis, and here we often fail. But I must say that to my knowledge extremely valuable work has been done by photography even of skin diseases. I may mention some work by Dr. Radcliffe Crocker, in London, and particularly I must allude to an *Atlas of Dermatology*, by Professor Piffard, of New York, of which I can only say that it is simply astonishing in its excellence of photographic rendering of skin diseases. And we have also dangers of misrepresentation and misapprehension to guard against, and here is an instance. When Koch's tuberculin was first used in this country I had under observation, personal and photographic, a female with severe *lupus* of the face. I photographed her before the use of tuberculin, and after a very marked improvement had been produced by the tuberculin. In the latter photograph she looks worse than in the first, simply because I under-exposed the negative in the second instance. Where, however, we have to deal with abnormalities of shape, with tumours, with malformations, with dislocations, and the like, we have in photography an invaluable aid to useful, educational, memory-refreshing record.

I now turn to what is more particularly my own province—Photomicrography; and it is not my intention to give you a lecture on histology, nor on any other medical branch of study. I propose simply to show slides which are put forward as illustrating some of the uses to which this branch of photography may be put in medical recording and teaching. And, first, I am aware that many students are kept from taking up this branch of work—so useful and so pleasant—by the idea that very expensive lenses are essential to success. That this is a mistaken notion I shall try to show by this slide of the blowfly's tongue. I did this negative and the slide from it this morning; and the objective with which the negative was produced was taken at random yesterday from a very cheap "student's" microscopic outfit in the shop of Mr. Crouch. I am rather averse to mentioning names in this way, but I see no reason why I should not do so this time. The whole outfit is priced at five or six guineas, so the price of this two-third objective cannot be great; yet, as an expert, I say that the slide now shown would "take a lot of beating" with any glass, however expensive.

The next three slides illustrate the advantage of photography in demonstrating facts which can only be proved by specially fine, or even accidental, preparations. Many sections might have to be cut before we could find ossification of cartilage, mucous glands in the trachea, or taste-buds in the tongue, as they are shown here in Dr. Klein's preparations. The next slide shows some very curious cells in *epithelioma:* I have a collection of thirty or forty such peculiar cells in this disease. The next two are for purposes of comparison between some cells in epithelioma and certain animal organisms found in a disease of the liver to which rabbits are very liable. The question before us now is simply whether by means of photography we can well compare these two objects, and I submit to you that we can.

Some professors, engaged in teaching, have often suggested to me that it would be very useful to show to students the objects on the screen stained as nearly as possible similarly to the objects themselves. By the process of Lumière, of Lyons, published by that firm in France, and in a modified form by myself, I was able to gratify the wishes of my friends the teachers; but you probably will be of my opinion that the results, though they have the desired colour, are not otherwise so good as slides on ordinary gelatine plates. This slide, showing cancer cells invading fat, was actually stained with the ordinary lithium carmine so commonly used in this kind of work. The next slide shows in a very satisfactory way striated or voluntary muscle, and this leads me to point out the frequent necessity of pre-

paring one's own objects when special results are required. Thus the slide of *epididymis*, now shown, could not have been produced from any preparation I have ever seen on the market or ever expect to see. I had to prepare it myself, and the section, if I remember aright, is not more than the 7000th of an inch thick; otherwise I would not have got all the cells round the periphery in focus at once at such a magnification as 650 diameters. This next slide shows part of the same periphery in the *epididymis* of another animal, and here we have the spermatozoa with their heads towards the periphery, and their tails towards the centre, in the orthodox manner. This slide of *ciliated epithelium* I used lately at a public lecture to illustrate one way in which foreign matter is prevented from reaching the lungs. I explained the remarkable action of these lashes; but I did not think it necessary to say that this cell was taken from a frog, not from a man. This flagellum of *bacillus termo* is perhaps the smallest object ever photographed for itself alone. Dr. Dallinger has calculated its thickness as not more than the 200,000th of an inch. This flagellum is extremely difficult to stain, extremely difficult to see even when stained, and consequently not practically available for teaching purposes, unless photographed as here.

This slide shows a device of mine for demonstrating to an audience the *size* of micro-organisms. The cover-glass of the slide is a positive from a negative consisting of ruled squares having each side exactly one-tenth of an inch long. Here, then, in this square on the screen we have seven cocci, separate, not touching each other. The original magnification of the negative was 1000 diameters, consequently you see that in the square, of which each side is the 10,000th of an inch, we can with ease put seven of these cocci. The next slide shows an object very difficult to obtain because of its rarity, and so not usually available for class demonstration, *filaria sanguinis hominis*, lent me by Dr. P. Manson. This animal infests the blood of negroes in certain countries, disappears for twelve hours daily, and causes a very curious and severe disease.

A small glass box containing a layer of gelatineous material compounded so as to form a suitable culture medium for ordinary bacteria, was opened for a definite time on Wandsworth Common. You see here the number of colonies of bacteria which during the given time found their way to the given area of gelatine. In the next slide you see a precisely similar box, containing a precisely similar culture medium, opened for an equal time in Oxford-street. Here we have many more colonies than we had in the Wandsworth slide. This pair of slides represents part of a scientific experiment, and I submit that photography here proved its value as a simple and trustworthy recorder. The slides are from negatives by Mr. E. C. Bousfield. There is sometimes discussion as to the way in which micro-organisms cause disease in the body, whether they act directly by their mere presence, or indirectly by poisons evolved from themselves in the body. Well, here, at all events, in this remarkable preparation of mesentery by Monsieur Pasteur, of Paris, it is evident that the *anthrax* rods are present in the vessels in such numbers that their very presence must constitute disease. These vessels are so completely blocked by the organisms that the whole region must be deprived of blood, and consequently degenerate or gangrenous. And this next slide, a portion of the same preparation more highly magnified, points to another subject much discussed at present—*phagocytosis*. Here are the rods evidently in the blood corpuscles, not over nor below them, but *in* them, for, as you see, both corpuscles and rods are in focus, though the magnification is considerable.

The next three slides are intended by me to act as proofs of a certain theory where other methods of proof had failed. This represents an entire section of skin from a rare skin disease. I found organisms in the sections, always in vessels, never outside of vessels, but attempts at cultivation of the organisms yielded no results. Consequently, it was important to show, if possible, that the organisms occur in the vessels, and not scattered about irregularly, as they might be if they came from the substances used by me in course of preparation. Here is a minute vessel, flask-like in shape; here it is again, more highly magnified, with organisms fairly well shown; this third slide, magnified 1000 diameters, puts an end to doubt, for the bacilli are demonstrated with certainty.

It has by some good authorities been argued that the bacilli of leprosy are not found in ordinary cells of the body, but that they form masses, and exude a "*glia*" strongly resembling a cell. The next three slides show *lepra* bacilli undoubtedly in ordinary cells, for we see distinctly not only the cell walls well defined, but the nuclei; in the second and third slides the nucleus has evidently been split up by the rods. The first preparation, by Dr. G. Thin, is of *pus* from a leprous ulcer; the second and third represent extremely thin sections of leprous tissue, cut by myself, and stained expressly for the demonstration of the relation of rods to cells.

I show, merely as a matter of general interest, two photographs of the bacillus of influenza. The first I photographed more than two years ago for Dr. Klein, who, having confined his experiments to guinea-pigs and mice, failed to complete the chain of evidence required by bacteriologists before they accept an organism as the specific one of a disease. A few weeks ago, Drs. Pfeiffer and Kitisato, of Berlin, using rabbits for their experiments, proved this organism to be the specific cause of influenza. Guinea-pigs and mice are immune from the disease, rabbits are liable to it. The last slide shows the organism nearly pure in the sputa of a patient; the previous one showed a typical cultivation of the bacillus in "broth."

In conclusion, I submit that I have proved the value of photography as a method of demonstration, of research, and of education in medical science. I have before urged here, and I here urge again, those who are practised in photography to give a helping hand to those who are engaged in the science which, of all sciences, is the most beneficial to humanity.

ANDREW PRINGLE.

STEREOSCOPIC PHOTOGRAPHY.

[Bath Photographic Society.]

THE subject which I have been asked to introduce for our consideration to-night, is one so full of interest that I regret it is not in the hands of some one more experienced than myself, having had but two or three years' practice in the art in general, and but a few months in stereoscopic work. Knowing too well the difficulties the secretaries of our societies have to encounter in order to find matter, or, at least, promise to bring it forward at these monthly meetings during the winter, I could not refuse to fill a vacant turn at this meeting. I ask, and I shall deem it a favour therefore, if members will please consider this paper and demonstration as an honest attempt of one of the youngest members of the Society to take part in the work of its meetings.

We frequently have the pleasure of being instructed and interested by lectures and demonstrations by the leaders, who we may regard as the founders of the Society, and, indeed, the subject before us to-night has, I believe, been ably dealt with in years past; still, that is no reason why we, who are now learners, should not submit our work to the criticism of others in order to get our errors corrected. Further, I consider that if this Society is to continue a successful career, as we all hope, much will depend on the share and interest taken by ordinary members in its work.

This, by way of apology, which I trust may prepare you to expect nothing very original in this paper and short demonstration. I shall endeavour to arrange and submit to you particulars of the subject before us which I have gathered from my reading, supplemented, of course, by anything my short experience may enable me to give.

Stereoscopic photography is not a new invention, and I think I may venture to say that in the fourth and fifth decades of this century it was practised more than any other system. I can well remember as far back as the years between 1850 and 1860 that the stereoscope and its paper slides were to be found in almost every country house. But the discovery of the dry-plate process and the rapid introduction of improved portable apparatus doubtless appealed to popular taste, and the fashion for change held the field and the stereoscope was cast aside.

It is notable that, after 1851, stereoscopic work gradually declined until it became almost extinct. As proof of this, if you look into modern works on photography you will find very little, if any, mention of the process. Captain Abney, in his *Instruction in Photography*, published in 1888, devotes one small paragraph to stereoscopic prints, which he says "were at one time greatly the fashion, and regrets their going out, as views never look so realistic as when seen in the stereoscope." In Burton's *Modern Photography*, published in 1890, no allusion whatever is made to the subject, nor do many others of recent date.

Enthusiastic workers who wish to see the process revived have contributed their experiences to the press, and it is to these articles one must go for guidance in use of modern apparatus and dry plates.

There is, without doubt, a great inclination on the part of many good photographers to hark back to this older process, and who will tell you they believe in what Sir David Brewster said forty years ago: "That, although the pictures are small when seen by the unassisted eye, by placing them in an instrument properly constructed they may be made to appear exactly as the original appeared to the photographer when he took the picture." On the Continent, Germany, Sweden, and Norway have regular exhibitions. Some there are, however, who declaim this tendency to go back, and ridicule the stereoscope particularly as giving illusions which are inartistic, &c. Some will say they prefer the whole-plate or larger picture because one can get more on it; but this, of course, is an

error, because given lenses of long and short focus it will be found the angle of the lens which is used to cover the larger plate will include no more than the short focus lens for the smaller plate three and a quarter inches square.

Others deride the stereoscopic picture because, they say, it is necessary to have recourse to a mechanical contrivance in order to see them. This is made the subject of a paper recently read before the Glasgow Photographic Society, a *résumé* of which recently appeared in the JOURNAL. The writer is evidently an old hand, with much artistic experience possibly, and I should be sorry to attempt to contradict what he says, or not to believe there may be something in his contention that the increasing rage for stereoscopic work is but a temporary fashion with photographers, just as tops and marbles are in turn among schoolboys. But, while he deprecates the use of the stereoscope, asserting that a better picture may be seen with one eye, I would venture to remind him that the abused instrument is not absolutely necessary in order to see a picture stereoscopically, and that the power of making two pictures coalesce, provided they are properly taken, may be easily acquired with a little practice. Some people's eyes can acquire this habit quicker than others, but, once acquired and learnt, the power is not easily lost. The writer at Glasgow winds up his paper thus: "As regards the utility of stereoscopic photography, I think that will be confined to instrument-makers and dealers in material." I have in my mind some excellent photographers who will hardly agree with him.

THEORY.

It is impossible, in a short paper of this sort, to enter deeply into the theory of the subject, and it must be sufficient to state briefly the laws which govern it. The word "stereoscopic" is derived from two Greek words—*Stereos*, solid, and *Scopeo*, to view. This effect can only be obtained by binocular vision or by the union of two dissimilar pictures, taken with a camera with two lenses or by a single lens from different angles. The space separating our two eyes, or the two lenses of the camera, form, as it were, the parallactic base of a triangle, and from this base, which varies slightly in width in different persons, being never less than two, or more than three and a quarter inches, the muscular power of the eyes enables them to converge on any object within reasonable distance; the nearer the object, the greater the convergence.

This convergence cannot occur when one eye only is employed, because of the impossibility to form the parallactic angle.

But, as I have already said, this power of convergence becomes less and less strong as it recedes from the base, until objects at a great distance are viewed by parallel vision. This is what gives us the power of estimating distance and of viewing an object solid in the stereoscopic picture—a solidity which sculptors and painters often vainly endeavour to imitate by the chisel or judicious shading with colour. We view our pictures, and look partly round the objects contained in them, especially those in the foreground, with our two eyes, and, as nature has fixed the separation of these optics at a space varying from two and a half to three inches from centre to centre, it follows that our pictures must not be more than this width in order to obtain correct stereoscopic effect.

CAMERAS.

With regard to cameras, we may consider that any camera is capable of taking stereoscopic negatives, although preference is now given to a binocular, *i.e.*, to one having two lenses, and taking both pictures simultaneously.

Larger cameras are now generally preferred. Any size will do, provided it has two lenses in an adaptable front and a septum inside. A square-bellows camera, fitted thus, size 8 × 5, is the one most in use, the advantage being that you get your subject larger, and in cutting out the picture for your slide, you are able to take or leave any particular part of it. How this is easily done I shall be able to explain when we come to the cutting and mounting of prints. For a long time, in the earlier days of photography, a single-lens camera was mostly used for this work, and in some cases the plan is still the best, and many subjects require the base of the parallactic angle to be so great as to render the employment of a single-lens camera absolutely necessary. For example, if we are going to take a view at a distance from the seashore, where objects at that distance could produce no effect of solidity when viewed with both eyes from the point of sight, everything would look flat, and in one continuous line; but, by taking a photograph of the coast at one point, and then sailing along for a mile or so in the contrary direction, and exposing the other part of the plate, we should increase the parallactic angle, and the subject would be depicted in relief, and the effect of solidity produced in the result pictures when combined in the stereoscope.

It is of the greatest importance, when two lenses are used, that both should be exposed simultaneously, hence this bar on the caps, both of which would be better replaced by a shutter, which I intend to have made. And, when a single lens is employed, the exposure must be made under exactly similar conditions. There should not be the least movement of the object between the exposures, and consequently the single-lens camera is not so applicable for photographs of anything likely to move out of doors. Movement of the subject in a stereograph is represented by an unsightly blur, which effectually spoils the picture.

A word with regard to lenses. It is pretty generally admitted, I find, that the single achromatic lens is best suited for stereoscopic work, especially for landscape, seascape, and ruins. The only objection is that, when photographing an architectural subject very close, the uprights are rather distorted, especially if you have no swing back, as in this case; but, unless this distortion is very excessive, it does not matter, as the stereoscope will rectify it, while, on the other hand, if a picture be taken with a doublet, and is perfectly rectangular, the stereoscope may upset it to a disagreeable degree.

Care must be taken to see that both lenses are well screwed down in their flanges; also that the camera is level. Here you will see I have taken precautions.

The exposure of the plate should be ample, and subsequent development not carried too far, or the result may be a hard negative, which is a constant cause of snowiness in the prints or transparencies, especially when green leaves of trees, shining roofs of houses, or white roads have reflected a lot of light into the camera. Among the prints on the table you will find some I have purposely included to show how seriously I have erred in this respect; and, although they may look fair prints to the eye, if you put them into the stereoscope, you will soon discover the faults to which I allude. Brilliant negatives, such as we aim to get with a single lens to make pictures for the album, seldom make nice pictures for the stereoscope, while a flat, miserable-looking print is greatly improved, and gives best stereoscopic effect. You will observe some of the American prints are decidedly flat in appearance.

A very good plan, with a print from a dense or brilliant negative, is to expose it to a good light without the negative before toning, and thus, by degrading the high lights, the picture will appear softer in the stereoscope.

It will be understood that, in order to obtain prints which will give correct stereoscopic effect, it will be necessary to transpose the parts of the negative, that the right lens picture may be presented to the right eye, and left to left.

Here we call for both skill and patience, which can only be obtained by much practice. To the want of care in cutting and mounting prints is due much of the depreciation of stereoscopic work. Even now, among those who wish to revive it, I learn there is a great amount of carelessness, if not ignorance, displayed in this important part of the process. A celebrated photographer, who a short time ago was asked to judge the slides sent in for a stereoscopic competition, criticises the work of the competitors rather severely. He says, "Some of the prints were simply comic; as if the authors belonged to some select society, whose motto was, 'How not to do it;' and, if so, they had succeeded, and might triumphantly cry 'Excelsior!'" A great many of the prints had not been transposed in mounting, giving, therefore, a pseudo-scopic effect, so that distance became foreground, and latter, distance. Others were unevenly mounted from the base, and required one eye to be higher in the head than the other, in order to see the picture.

One cannot impress too much upon those who would revive this beautiful art science, that it is not only insufficient to properly transpose the two pictures, but that they must be mounted on the same plane, and the slightest error there is in this direction the greater will be the difficulty in making the pictures combine in the stereoscope. The rule is, having settled the width of the two pictures, to select something in the foreground—a bit of round stone, or a fault in the ground, and to cut the base line through the two pictures at this line—the height may be left to take care of itself—and may often extend to four inches without inconvenience.

Beautiful as these paper slides are, especially when printed on good matt surface paper, there is nothing so good as a stereoscopic transparency. There is a selection on the table, and a few also of my own make, by a process which I hope to demonstrate successfully.

It is generally admitted, except by very prejudiced people, that a more perfect transcript of nature cannot be produced than by a well-printed stereoscopic transparency. But the care, precision, and practice which I mentioned as being so necessary in cutting and mounting prints applies even more to the making of these transparencies. A little error in the paper print may be set right, or eliminated entirely, by the help of the knife, but not so easily when one comes to transpose and print from glass to glass. Some photographers will cut the negative, and, having transposed the parts, print from it direct, as for lantern transparencies. This

plan, perhaps, is the best in the hands of an expert in the use of the diamond.

THE STEREOSCOPE.

Here we have an instrument known, I believe, as Holmes' Stereoscope, and which has been in use in America during the last twenty years, and is now finding a ready sale in England. There is no doubt, if this instrument had been introduced into England thirty years ago, stereoscopic photography would not have lost its popularity with the public. It certainly was the cause of raising my enthusiasm, and, having acquired an instrument and some pictures, I began to look about for a good camera to do some of the work myself.

Bad instruments, as well as bad prints, had much to do with the decline of public taste in regard to the stereoscope; but now, with the advance of the art of photography, dry plates of any speed, and improved apparatus for taking as well as viewing the pictures, I hope there is a good future in prospect for the stereoscope, and that many here, as elsewhere, may derive as much pleasure from it as I have done.

E. J. APPLEBY.

PHOTOGRAPHY AND PHOTO-MECHANICAL PRINTING.*

THE preparation of collotype plates is not difficult. The first thing necessary is a suitable oven, in which to dry the film of sensitised gelatine, for with this process rapid drying at a considerable heat is necessary. A large box with a sheet-iron bottom, which can be heated with Bunsen burners, answers very well, though hot-water pipes are preferable. This drying box should have a lid covered with canvas, to permit quick evaporation, and the interior must be fitted with adjustable points, on which the plates can be accurately levelled. There should also be a thermometer fixed with the bulb inside the box, so that the amount of heat can be readily adjusted. The chemical composition of the films is the same as that employed in photo-lithography, with the difference that the gelatine should be hard and very pure. The inking and printing of collotype plates is necessarily an operation which places a great strain on the holding power of a film of wet gelatine to its glass support, a pressure of several tons being sometimes required to obtain the impression on paper, and a powerful substratum is used to cement the printing surface to its glass support. The following is approximately the formula for the substratum :—

Albumen	10 ounces.
Water glass	4 ,,
Water	10 ,,

This solution is filtered and flowed over the surface of the ground glass, which is then dried after a slight washing. The plate is then ready for the sensitising solution, which is composed of—

Hard gelatine	3 ounces.
Water	1 quart.
Bichromate potash	½ ounce.

The glass plate is warmed, and the sensitising solution also warmed, and, after carefully filtering through flannel, is poured over the surface of substratum, and the plate is immediately placed on the levelling screws in the drying oven, and heat is applied. The drying ought to occupy about half an hour. When the plate is dry, it is ready for exposure under a negative. Here is a plate ready for exposure. We ought to mention, the negative must be reversed, that is, if what is called a right-hand picture is desired. There are several ways of reversing negatives; direct in the camera, by means of a reversing mirror, or even by placing the plate in the dark slide wrong way about, first carefully cleaning the glass side of the plate, and allowing for the thickness of the glass in focussing; but the most generally adopted methods are, first, by stripping the films from their original glass, and turning them over on to another one; and, secondly, by making a transparency and copying it in the camera through the glass.

Having obtained a reversed negative, the margins should be masked to the size of the required print with thin black paper or tinfoil, and placed, with the sensitive collotype plate, in a printing frame for exposure. The time required for exposure will, of course, vary according to the density of the negative and to the quality of the light; and, as the plate cannot be examined during exposure, an actinometer is used to measure the amount of light falling on the plate. Experience is really the only guide as to correct exposure, but the average time in a moderate light may be taken as half an hour. After exposure, the plate is removed to the dark room, and is placed in running water for about half an hour to wash out the unacted-upon bichromate, after which the plate is allowed to dry spontaneously, and it is then ready for printing. (Here are exposed plates, one plain and one inked.)

The printing may be performed in an ordinary printing press, with a sheet of indiarubber over the tympan, or, as is most in vogue, in a lithographic press. The plate is first damped with a sponge and water, as Mr. Geddes is now doing, and, after wiping the surface dry, ink is applied, first with a leather roller for the purpose of inking up the shadows and stronger parts of the picture, and then, with a gelatine roller, to give ink to the half-tones. A piece of ordinary paper is now placed over the inked image and pressure is applied, the result being, if all goes well, a permanent photograph in printing ink from the negative used. If ink of a photographic or silver print colour is used, and the paper is afterwards enamelled, the results are to all intents and purposes a photograph.

Before we conclude, we must just mention one of the most interesting and fascinating phases of collotype printing, and one which is as yet only in its infancy. We refer to chromo-collotype, and will venture to say it is the nearest approach to the much-sought-for process of photography in natural colour. In this process use is made of the fact that all colours emanate or are produced from the three primaries, namely, red, blue, and yellow, and, by the aid of specially sensitised colour plates and our knowledge of orthochromatic photography, we are enabled to analyse the colours of a picture, and produce three plates which have the property of photographing the particular primary colours for which each one is sensitised; then, by printing these three negatives in their separate colours, one over the other, by collotype, using a transparent ink, we obtain very approximately the actual colours of the original picture or landscape. We cannot go into this matter further now, as the time at our disposal is short, and the entire process is too complex. We have here some examples of this work, upon which we have recently been making a series of experiments, and there are specimens printed from the negatives of each colour as well as complete proof printed in the three colours and registered one over the other, viz., red, blue, and yellow.

PAUL L. WATERLOW.
J. D. GEDDES.

* Concluded from page 249.

A PHOTOGRAPHERS' HALF-HOLIDAY.

IT will be remembered that a few weeks ago we mentioned that several of the Greenock photographers had resolved to close their establishments for one afternoon per week, in order to give their assistants a holiday. A similar movement has recently been started in Glasgow, where, we are glad to find, it has met with great favour among the photographers, the under-mentioned houses agreeing to close their places of business during one afternoon of each week :—

Friday, three p.m.: A. Macnab, Brinkley & Stevenson, Turnbull & Sons, G. Bell, Crawford Hamilton, James Philson, Watson & Wilson, Robert T. Dodd, James Whyte, Glasgow Photographic Company, Robert Ness, Forbes & Co., William Gemmell, William Hall, William Hicks, Ovinius Davis, A. & G. Taylor, W. Hampton, M. Pearlman, T. W. Stevens, A. Finlayson, Stevenson & Co., Patterson & Co., W. Warneuke. Saturday, three p.m. : John Stuart, Limited, T. & R. Annan & Sons, William Ralston, Alexander Brothers, Mons. Lafayette. Two p.m. : Adamson Brothers. Wednesday, three p.m.: Ralston & Sons, — Mitchell.

According to the terms of the agreement the movement comes into operation in the first week of May. We congratulate our Glasgow friends on their just and considerate action, and, in the interests of photographic assistants generally, we trust that it will receive a large degree of imitation in other parts of the country. Mr. J. J. Moran (of Messrs. Turnbull & Sons, Glasgow) has taken an active part in the movement, the success of which must be very gratifying to him.

LONDON AND PROVINCIAL PHOTOGRAPHIC ASSOCIATION.

APRIL 14,—Mr. A. Cowan in the chair.

Messrs. A. Dawson and H. W. Bennett were elected members of the Association.

The following questions from the box were read:—"What is the best way to correct the acidity of a glue mountant to ensure its keeping?" To this no definite answer was forthcoming; but in reply to the following, "With which developer can the harder negative be produced, pyro-potash or pyro-ammonia?" Mr. F. P. CEMBRANO said, if anything, with pyro-potash.

The evening was chiefly devoted to the exhibition of a large number of lantern slides, illustrative of some of the places visited during the Convention weeks at Derby, Birmingham, Chester, and Bath. The slides were the work of Messrs. F. P. Cembrano, jun. (the Honorary Secretary of the Convention), and Mr. H. M. Hastings, by whom they were shown in the lantern, the former gentleman, prior to the exhibition, expressing the hope that the beauty of the places visited would induce larger attendances at future Conventions.

At the conclusion of the display (which included a few slides of the recent University boat-race by Mr. H. M. Hastings) the thanks of the meeting were tendered to both gentlemen, and the proceedings terminated.

The Lantern Society.—April 11, Mr. E. M. Nelson in the chair.—A lecture was delivered by Mr. E. W. MAUNDER, F.R.A.S., on *The Work of the Spectroscope as applied to Astronomy*. In commencing his address, Mr. Maunder remarked that the title which had been announced for his lecture was of somewhat too broad a character, and that, inasmuch as it would be impossible, within the time at his disposal, to even touch upon the numerous branches of spectroscopic work connected with astronomy, he proposed to confine himself chiefly to the application of the spectroscope to solar researches, adding some remarks on stellar spectroscopy. Commencing with Newton's researches on the composition of light, and the subsequent experiments of Wollaston and Fraunhofer, Mr Maunder went on to explain the principles on which a spectroscope was constructed, and to describe some of the chief varieties of the instrument now in use. The discovery of the Fraunhofer lines, and the experiments of Kirchoff, proving that these dark lines were due to the absorption of certain rays by incandescent gases, the mapping of these lines by Angström in the solar spectrum, and their identification with lines due to the presence of certain terrestial elements in the solar atmosphere, were next dealt with, Angström's chart of the normal solar spectrum being thrown upon the screen. As showing the great advance which has of late years been made in the study of the solar spectrum, Mr. Maunder also showed on the screen portions of the magnificently defined spectra recorded photographically by Mr. George Higgs, of Liverpool, whose arrangement of spectroscope, devised (with the exception of the diffraction grating) wholly constructed by himself, was also illustrated by a lantern slide. Dealing next with solar physics, Mr. Maunder described the structural features of the sun so far as they are at present understood, touching on sun-spot periods, the peculiarities of sun-spots during the periods of maxima and minima as revealed by the spectroscope, the constitution of the chromosphere, and the application of the spectroscope to the observation of prominences, which, prior to such application, had only been observable on the occasion of total solar eclipses, when the sun's disc was obscured by the dark body of the moon. The latest development in this particular branch of research—namely, the photographing of the solar prominences by Professor George Hale at Chicago—was also described and illustrated. After speaking briefly of the spectra yielded by the planets, Mr. Maunder next dealt with cometary spectra, pointing out the resemblance of what may be called the normal spectrum of a comet to that of carbon in olefiant gas, and showing how, as some comets had passed very close to the sun, their spectra had shown indications of the presence, first, of sodium, and (when still closer to the sun) of iron in a gaseous state. Next Mr. Maunder dealt briefly with the chief features of stellar spectroscopy, describing the mode of observing and photographing stellar spectra adopted at Harvard College Observatory, and explaining the principles on which the velocity of stars in the line of sight is measured. In connexion with this department of the subject, the discovery of the duplicity of β Aurigæ by Professor Pickering, solely by the variations in its spectrum, was described, while, finally, some interesting notes were given on the recent new temporary star in Auriga, the spectrum of this star being thrown on the screen, and its special features explained in detail. The lecture was illustrated by a large number of lantern slides, and was throughout a most interesting one. The next meeting of the Lantern Society will be held on Monday, the 25th inst.

Dundee and East of Scotland Photographic Association.—April 7, Mr. J. D. Cox (President) in the chair.—A demonstration was given of the stripping and enlarging powers of "Cresco Fylma." A quarter-plate transparency was successfully stripped and enlarged to fully 5×4. The process had been found useful in the hands of the demonstrator for saving cracked negatives. Mr. D. Ireland exhibited 140 slides, being part of his Norwegian work last year. Mr. Feathers exhibited the Ideal and Shuttle hand cameras. Prizes were awarded in the under-noted competitions as follows:—Junior Lantern-slide Competition: 1st, J. S. Lawson; 2nd, J. M. Wilson; 3rd, Dr. McGillwray. Bromide Print Competition: 1st, J. McInroy; 2nd, D. Ireland; 3rd, Dr. McGillwray.

Correspondence.

☞ *Correspondents should never write on both sides of the paper.*

PHOTOGRAPHY AND THE DETECTION OF CRIME.

To the EDITOR.

SIR,—The interesting collection of photographs, and the paper accompanying them, now being circulated amongst the photographic societies under the affiliation scheme, seem to be much appreciated wherever they are exhibited. But I think the paper, interesting as it is, would have been still more so to the majority of those before whom they are exhibited had the methods employed to obtain the striking effects—striking as compared with other photographs taken under normal conditions—been explained. The Doctor, in his paper, several times refers to "my method," but does not describe what that method is, and wherein it differs from those usually adopted. I presume, therefore, as he makes a specialty of this class of work, he prefers, as a matter of business, to keep the details of his method, or modes of procedure, to himself. Be that as it may, the photographs by themselves are none the less interesting or valuable, as showing what may be accomplished in the application of photography in the detection of crime.

Of course, what Dr. Jeserich has achieved others may accomplish if they gave sufficient time and attention to the subject. I should not be surprised if the prominence now being given to the topic, by the exhibition of the slides, acts as an incentive to others to go into the subject as a matter of business in this country. Clever experts in such matters as those Dr. Jeserich has taken in hand might find the business highly remunerative, particularly after they, like the gentleman named, have gained some notoriety. For example, in questions of forgery or the falsification of documents, like some of the examples in the collection, large sums would frequently be paid for incontestable proof of the falsity or the genuineness of the writings. At present the chief evidence relied upon here in such cases is that of experts in handwriting and that is often received—and not without reason—with a considerable amount of hesitation, especially when experts are engaged by each of the contesting parties.

This brings me to the question. Supposing several photographers made a specialty of this particular class of work, as Dr. Jeserich has done, and some were engaged by one side in a suit to prove that, say, a deed had been tampered with, and others were employed by the opposite side to show that it had not. The latter, by taking the negatives under ordinary conditions, might show that a pure photograph exhibited no falsification whatever, as in the case of the Doctor's comparative plates. The former, working under modified conditions, might in their photographs show that a fraud had been committed. Here would, of course, be a direct conflict of evidence, quite as great as that frequently given by experts in the case of handwritings. The one would be quite justified in asserting that his was a pure, unsophisticated photograph, and it, like the original before the Court, exhibited no trace of alteration. The other, under cross-examination by a shrewd counsel, would be compelled to admit that in order to obtain his results the photograph, which differed from what could be detected by the eye, had been taken under modified conditions and by a special treatment or method of working. This might be construed by a non-technical jury, influenced by the arguments of a clever counsel, into a sophistication of the photograph.

It is unfortunate for the credit of the art that photographs are now looked upon with a certain degree of doubt in British Courts of Law, and rightly too in many instances. Here is a case in point. I was recently shown a photograph taken to prove damage in a case of "ancient lights." It certainly fulfilled its object, for it showed a strong cast shadow of the new erection right across the windows claimed as the ancient lights. But it was, nevertheless, a very misleading picture, inasmuch as it was taken under exceptional conditions, that is, very late in the evening, when the sun was setting, consequently it produced very long shadows. Had it, or another picture, been taken earlier in the day, no such obstruction would have been shown. However, the picture was accepted as a proof that injury was sustained, and a good sum was paid as compensation in order to avoid further costly litigation.

On one or two former occasions you have suggested that the police authorities do not, officially, make so great a use of photography as they might do in the detection of crime. It is true that all convicted criminals are photographed, and the portraits systematically arranged and preserved. But a much more extended use might be made of it in furthering the ends of justice. Often, when, say, a murder or other outrage has been discovered, if a photograph, or a series of photographs, were taken of the immediate surroundings at once, before anything was disturbed, it would frequently aid in settling matters sometimes left in doubt. Frequently it happens that the evidence adduced as to the precise condition or position of certain things at the time of the discovery are very conflicting, a thing not to be wondered at considering the excitement general at the moment. Notably was this the case in connexion with one of the East-end tragedies, and also in others. But a photograph, if forthcoming, would put matters beyond all question.

There is no place where, or rarely, conditions under which a photograph good enough for all purposes cannot be taken, even if not reached by daylight, thanks to gelatine plates and magnesium. The time, I hope, is not far distant when an official photographer will be attached to every police division under conditions similar to those under which surgeons and others are now appointed.—I am, yours, &c., LEX.

April 16, 1892.

RATIO OF GRADATION.

To the EDITOR.

SIR,—In your last issue "Free Lance" seeks to throw on to me the onus of treating this matter as a burlesque. In a former letter I showed that the recent utterances of Messrs. Hurter & Driffield are at one with their original paper, and consequently that there was no ground for charging them with "ignorance of their own work such a short time after its publication." I called attention to "Free Lance's" opinion anent "the universal practice of photographers to alter the ratios by modifications or changes of development," that the ratios "can be changed at will." I inquired how he could change them, and in reply I have nothing but a vague reference to a trivial variation noted by Messrs. Hurter & Driffield, which "Free Lance" has evidently not forgotten.

In order to meet the obvious reply that the ratios remain practically unaltered by the variation in question, he states that the words "almost identically the same" are without meaning in a scientific question!

I must, for the present, conclude that "Free Lance's" knowledge of altering the ratio of gradation is derived from Messrs. Hurter & Driffield's observations; and that, did he know more of their writings, he would know more of this subject. It would also appear that he has been having a quiet joke with the readers of the JOURNAL, as one who should say, "I think I can find you bread to eat," and offer a crumb from the last loaf. Of course, a joke is a joke, though it may be a bad one.

May I take this opportunity of replying to a question that has been put, more than once, by the Editor to correspondents, as to the possibility of a latent image "setting off" on to an unexposed plate? I exposed a piece of bromide paper behind a negative to sufficient light to produce a vigorous image. I then moistened the paper, and squeegeed it face to face with an unexposed piece of similar paper. I developed the compound for upwards of an hour, until the image was well visible when held up to the light. The papers were then pulled apart, and the image was found to be entirely on the exposed paper. I think this should allay all fears of the setting off of the image from plate to plate; but how is it to be reconciled with Captain Abney's experiment of coating a gelatine plate with collodion emulsion, and developing the two in contact? Will some one who has a bottle of collodion emulsion repeat this experiment? It may be that some plates are phosphorescent, and others not; it is, however, of importance to set the matter at rest. The general conclusion is that a particle of developed silver compound reduces contiguous particles unaffected by light. The equation of Messrs. Hurter & Driffield does not assume this, but is grounded on the supposition that only particles altered by light are developable. This is apart from general fog, caused by the action of the developer on silver unchanged by light, and irrespective of its contiguity to changed particles.

My thanks are due to Mr. Channon for his reference to Captain Abney's original paper. His reproduction of Captain Abney's figures interests me exceedingly, and I should like to suggest a possible explanation of the difference found from the law of Hurter & Driffield. These state that the law holds only for some substances, not for all; and they especially mention silver reduced in a film as long *as it does not assume a metallic lustre, nor reflect much light*. But if Captain Abney first threw down the silver, and then incorporated it with gelatine, the particles would probably have great lustre, and by reflections and re-reflections appear much more transparent than would dull granules. The subject is full of interest, and I shall be glad to hear anything which may assist in its elucidation.—I am, yours, &c., R. C. PHILLIPS.

Arts Club, Manchester, April 18, 1892.

To the EDITOR.

SIR,—We received a private communication from Mr. Channon, asking us to take no notice of his letter in your issue of the 1st April, as he had very considerably altered his opinions, and as he intended to send another communication to the JOURNAL. We have waited for the appearance of his third letter; but, as it has not come forward, we feel it necessary to briefly reply to the second.

Mr. Channon, like others of our critics, shifts his ground. In his first letter he opposed Plener's formula to our own as superior for mathematical reasons. Finding, however, that Plener's formula could not be supported by clear reasoning, involving a consistent definition of the symbols used, he abandons this formula in his second letter, and opposes us with Captain Abney's *Law of Error*. This *Law of Error* we have criticised elsewhere, and we are reluctant to add anything to that criticism at present, though there is much yet to be said about it. From Mr. Channon's letter to ourselves we gather that he has now abandoned the *Law of Error*, and we are at present waiting to learn what he has to put in its place.

To our request for a sample of plates differing in behaviour from those we have investigated, and to which the formulæ we published do not even apply approximately, Mr. Channon has not acceded, nor has he again mentioned the subject. It is fair to conclude that he is still in search of such plates. When he has found them, we shall be glad to investigate and report upon them.

May we remind Mr. Channon that formulæ, to be satisfactory, must account at least for the phenomena of under-exposure, over-exposure, and correct exposure; and that neither Plener's nor Captain Abney's formulæ will do this; that these formulæ must be simple, if they are to admit of practical applications; and that they must also account for certain peculiar relations which exist between negatives and their positives.—We are, yours, &c., F. HURTER & V. C. DRIFFIELD.

Appleton, Widnes, April 16, 1892.

[In justice to Mr. Channon we should state that his interesting communication, which appears elsewhere, was unavoidably held over from our last issue.—ED.]

BACKGROUNDS.

To the EDITOR.

SIR,—In reply to your request for information for "McDawber," Messrs. J. Williams & Co., Langley Mills, Manchester, manufacture a strong sheeting suitable for backgrounds, all widths up to nine feet. I have an eighteen feet screen made by them with only one joint, and, speaking from memory, I think the price was 3*s*. per linear yard.—I am, yours, &c., EDWARD J. SMITH.

Park Royd, Halifax, April 18, 1892.

To the EDITOR.

SIR,—In reply to "McDawber," any large drapery establishment doing a family trade will be able to supply *good* white sheeting, also linen, which would be preferable. People who buy the unbleached seldom have beds that require sheets more than two yards wide.

In making application for prices and patterns, he should ask for eleven or twelve-quarter (the former would be about eight feet wide), requesting that it *be not less* than the exact width wanted; a few inches over would not matter.

Personally, I have seen it at Swan & Edgar's, Piccadilly-circus, W., and other large West-end draperies.—I am, yours, &c.,

Stradbroke, Suffolk, April 16, 1892. WM. GIRLING.

MODIFYING LENSES.

To the EDITOR.

SIR,—The formula for calculating the focus of combined lenses given in my paper (THE BRITISH JOURNAL OF PHOTOGRAPHY, March 18) should have been $\frac{A \times B}{A+B-C}$ as stated by Mr. George C. Pile. It was written so in my manuscript, and the error, as printed, is so striking that it can only be due to the printer.—I am, yours, &c., HENRY W. BENNETT.

April 20, 1892.

PHOTOGRAPHY AT BIARRITZ.

To the EDITOR.

SIR,—As most of my photographic friends are not aware of my present abode, I write a line to say I am here with my camera and lantern. I have registered a vow not to bring again the latter abroad, as the difficulty of getting a supply of oxygen is considerable and the price excessive.

Biarritz during the winter and spring months is taken complete possession of by the English. As you walk through the streets, on the Grande Place, or sit on the rocks, the sound of the well-known tongue falls on your ears, for our language now is the most universal; and whether, when it covers this world, as, if it increases in the same degree, it gives rise to any Babel confusion, is a matter on which some may speculate.

The hotel-keepers, proprietors of villas, and shop folk are well favoured here, as there are only six weeks in the year when Biarritz is without a season. The English season commences in November, and lasts until May; then comes the interval until the 15th of July, when the place is empty. The Spanish season is then on, it being the great event of the

year. During this time prices become nearly double, and the Spaniards bleed freely, preferring English artists to all others. After the Spanish season comes the Russian—October to a part of November.

But, although the summer is the bathing season, bathing is going on now, and ladies were seen swimming in the Port Vieux on the 17th March. On the 5th of April I saw a party, of six ladies and four gentlemen bathing in the same place, and I took a photograph when one of the former was taking a header off a rock. It is well to mention that the temperature was at the time 78° in the shade. As regards temperature, Biarritz holds a good standing. I have kept a rough mem. for the last fifty days, and I find that at nine a.m. the average temperature was, in the shade, 62°. On a few days, when, even in Italy, snow lay on the ground—March 4 to 7—the thermometer at nine a.m. varied from 35° to 37°, but no snow; of course, during the advance of the day the temperature increased, and I noted one day, at 3.30, the temperature rose to 79°. Then, as regards sunshine, out of fifty days there were forty bright, sunny, dry days, ten being rainy, without sun.

Biarritz does not afford many subjects for photography beyond sea and rocks—the latter are not particularly striking. I expected great things from the Bay of Biscay, but found it, on most days, very tranquil. I was informed I would see waves slowly advancing like a great wall of twenty feet, then suddenly falling on the shore. These I did not see, although I daily looked for them. A friend of mine, who has resided here for four years, has not seen such. His remark to me on the subject was, "These are to be talked about, but not seen."

As regards my lantern. After much trouble in the pursuit of oxygen gas, I discovered that some was kept in Bayonne for medical purposes. It was sold in large cylinders, holding 200 litres, at a pressure of eight atmospheres, which, I was informed, was equal to fifty-five English gallons, or to about forty-six English feet at 120 atmospheres; but it only lasted, when burnt in the lantern, for two and a half hours. I find, when using my twelve-feet cylinder of 120 atmospheres, I can get nearly four hours out of it, costing 3s., while the Bayonne gas cost me 14f. (11s. 1d.) for two and a half hours, or about 1l. for what in England costs 3s. The quality of the gas was excellent, and I do not think I ever had such a brilliantly lit screen. My spectators were much pleased; it was the first time the limelight was ever seen in Biarritz, so that I have made a decided score in this instance. I leave to-morrow for the Pyrenees.—I am, yours, &c.,

T. M. Brownrigg.

The British Club, Avenue du Palais, Biarritz, April 12, 1892.

ATMOSPHERIC PERSPECTIVE.

To the Editor.

Sir,—Allow me to supplement your reply to F. Baxter (issue of 15th) by pointing out that the over-exposure of No. 2 plate was probably due to the fact that, owing to the greater distance at which second view was taken, the light from a much greater area was focussed on to the same-sized plate. I was some time in tracing this source of error, and was led to it by noticing that my over-exposures were principally on plates which embraced an extensive view. I should expect the atmosphere amongst the Welsh hills to be pretty clear, and have myself successfully photographed and got clear negatives of objects at a distance of a quarter of a quarter of a mile, and have seen many bright photographs of Swiss and other scenes which must have been taken at a greater distance than that.

In taking negatives which embrace an extensive view, I now either shorten the exposure or stop down the lens.—I am, yours, &c.,

April 18, 1892. Clare.

"PHOTOGRAPHIC PORTRAITS."

To the Editor.

Sir,—The intentions of your correspondent Mr. Cimabue Brown, jun., in seeking to find some excuse for vulgarity are no doubt creditable to his kindness of disposition, but, at the same time, based, I think, on a misconception of the case. It is, of course, impossible to prevent foolish and vulgar people from writing foolishly and in bad taste under the cover of anonymity. My object was, however, to call attention to the responsibility of the Editor of the journal in question, and to suggest that he could not have been aware of the nature of the communication.

I can hardly imagine that opticians as a body, or rather, perhaps, I should say makers of optical instruments, can, as your correspondent suggests, be in sympathy, under whatever provocation, of such methods as their trade organ (as Mr. Brown calls the journal in question) has used. It would be a libel upon them to suppose it. And, again, what has been the provocation? I admit, for myself, that I have written elsewhere that "a first-class lens has no more artistic value than has (in literature) a first-class pen." But, Sir, the opposition amongst photographers, if I may be allowed to call it so, is never tired of asserting that no art is possible in photography. They hail with evident delight and glee opinions such as those expressed by Mr. Joseph Pennell at meetings when the subject is discussed. If that, then, is their view of the matter, if no art is possible, why find fault if we assert that the most perfect of optical appliances cannot import art into it? Again, supposing that for half a century or more numbers of misguided people had been in the habit of using double convex lenses of the highest quality, free from astigmatism and all the rest of it, say, as soup-plates, and that the doctrine were suddenly preached and disseminated that common delf, of a concave pattern, would be more useful; or, with greater hardihood, if it were asserted that the total suppression of such optical instruments, and a return to the purer and more primitive method of forming a bowl in the hollow of the hand would be productive of better results, would the opticians be justified in exclaiming, "It is true people are foolish; but, at at the same time, we are enabled to sell them large quantities of our goods, with which they fruitlessly endeavour to attain the unattainable; if you promulgate your doctrines, they will come to their senses, and our trade will be ruined?" I think not.

Mr. Cimabue Brown, jun., holds that what he calls the new school may be distinguished in future by the mark, "No lens, no brains." Now, Sir, this is, of course, only an assertion, which, on high authority, would no doubt demand grave and earnest consideration. But, if Mr. Cimabue Brown, jun., is a great and weighty authority, to my shame I must confess that I never heard of him before. I am inclined to surmise, however, that the name is but a pseudonym, veiling, perhaps, the most distinguished identity; but, until we know this, subject to the inevitable depreciation of value which, as a general rule, attends the outpourings of anonymous contributors. But, supposing the epithet to be, in this instance, well applied, it will be remembered that I challenged our opponents to name half a dozen expounders of the new system, a challenge which has not yet been taken up. Is it reasonable, then, to expect that we should find a large volume of brains amongst so few? Oh, pray do not let it be imagined for a moment that I accuse Mr. Cimabue Brown, jun., of inferring that the quality of the brains has anything to do with the matter! We know, of course, that more brains must be found amongst the multitude than can be possessed by a lesser number. By the way, though, Mr. Cimabue Brown, jun., refuses to concede, by his formula, any brains at all—"No lens, no brains."

Seriously, Sir, I cannot imagine that opticians are at all alarmed by the idea that the exhortations of the poor little band of brainless ones is likely to deprive the optical trade of their usefulness and means of livelihood. King Sol himself might as reasonably get red in the face with indignation at the advent of Mr. Humphrey's oxy-magnesium lamp.

Mr. Cimabue Brown, jun., must, I think, find some other grounds of excuse.—I am, yours, &c.,

Alfred Maskell.

London, April 17, 1892.

THE CHICAGO EXHIBITION.

To the Editor.

Sir,—May I ask you to give publicity to the fact that, Her Majesty's Government having increased to 60,000*l.* the grant of 25,000*l.* originally made for the purposes of the British Section at the Chicago Exhibition, the Royal Commission for that Exhibition are enabled to dispense with the revenue it was proposed to raise by charging the exhibitors in proportion to the extent of space occupied, and that, therefore, all space in the British Section will now be granted free of change.—I am, yours, &c.,

H. T. Wood, *Secretary.*

Society of Arts, John-street, Adelphi, W.C., April 19, 1892.

Exchange Column.

*** *No charge is made for inserting Exchanges of Apparatus in this column; but none will be inserted unless the article wanted is definitely stated. Those who specify their requirements as "anything useful" will therefore understand the reason of their non-appearance.*

Will exchange Dallmeyer's 2c Baby lens (very rapid) for stylish studio accessories.—Address, Dagay, Stowe, Bedford.

Whole-plate portrait lens by Lerebour in exchange for cabinet lens by good maker.—Address, Artist, 65, Dale-street, Batley Carr.

Will exchange two full-size backgrounds, nearly new, for cabinet portrait lens (short focus).—Address, 21, Station-street, Sittingbourne.

Wanted, rapid rectilinear for 15×12 landscape by Ross, seventeen inch focus.—Address, E., 7, Forest Hill-road, Peckham, London, S.E.

A light and portable 12×10 camera, with two double backs, in exchange for complete half-plate outfit.—Address, 21, Station-street, Sittingbourne.

I will exchange a rectilinear lens, nearly new, for two backgrounds, interior and exterior.—Address, A. H. Scholes, 148, Shawclough-road, Rochdale, Lancashire.

Will exchange an enlarging apparatus with pair of seven-inch condensing lenses [illegible]'s, cost 6*l.* 13*s.*, for 12×10 landscape camera.—Address, W. K., 104, Terminus-road, Eastbourne.

Wanted, a strong, whole-plate studio camera stand in exchange for a "Vogel" cabinet and whole-plate portrait lens, or twelve-inch burnisher by "Vevers."—Address, Hughes, photographer, 26, Caroline-street, Cardiff.

12×10 camera, with two double dark slides, in exchange for complete half-plate outfit; also two full-size backgrounds (interior and exterior) for cabinet portrait lens or studio accessories.—Address, H. Wakefield, 21, Station-street, Sittingbourne.

Superior quarter-plate mahogany camera, all movements, three double dark slides, 5×4 rapid rectilinear lense, in leather case, quite new, cost 7*l.*, exchange for "Ideal" hand camera.—Address, J. Stevens, 89, Balcombe-street, London, N.W.

Wanted, a press for cabinet and cartes (enshion dies) in exchange for whole-plate view lens, also quarter-plate portrait lens and camera for a retouching desk with reflector and drawer from quarter to 10×8.—Address, Jas. Hurnott, 8, Castle-gate, Berwick-on-Tweed.

Answers to Correspondents.

All matters for the text portion of this JOURNAL, *including queries for "Answers" and "Exchanges," must be addressed to* "THE EDITOR," *2, York-street, Covent Garden, London. Inattention to this ensures delay. No notice taken of communications unless name and address of writer are given.*

**** Communications relating to Advertisements and general business affairs must be addressed to* "HENRY GREENWOOD & Co.," *2, York-street, Covent Garden, London.*

1, 2, 3.—Apply to a dealer.

AUGUST BAER.—Received with thanks.

Z. K.—Cresco-fylma is the subject of a patent.

BROMO-CHLORO.—We do not know of any method of restoring the energy of a used pyro developer.

C. H. J. (Chicago).—The fewer the reflecting surfaces in a lens, the more rapid ought to be the exposure.

ILIAD.—We should recommend you to repeat the experiment, and pay greater attention to the directions given in the paper.

ILEX.—No; chemically pure chloride of sodium is not necessary in precipitating silver nitrate as chloride, although preferable.

R. W. A.—From the description given, the mottling arises from the plates not being "rocked" sufficiently during the development.

T. WARREN.—Unless we saw some of the examples, it would be impossible to help you. The details furnished are contradictory in themselves.

A. A.—Write personally to the manager. Your letter was, doubtless, replied to by a clerk who knew nothing of the technical part of the business.

ALTON.—Perhaps the better plan for you to pursue would be to apply a weak reducing solution to the negative, to remove the veil, and then intensify it.

PHOTOGRAPHER (Burton-on-Trent).—There is only one nitrate of silver, and not two. If you order that, you will get the right article for making dry plates.

WHITE LEAD.—We should not apprehend any deleterious effect on your silver prints arising from the use of white lead in making good the joints of the wood diah.

A. G. C.—You seem to have done everything to discover the cause of the foggy appearance of your plates except one thing, and that is, to examine your camera and slides for "light-tightness."

J. M.—If you will consult the articles by Mr. W. B. Bolton at pages 260, 308, 325, and 356 of this JOURNAL for 1888, you will find complete information on the subject of gelatino-bromide opals.

C. C. W.—The lenses of the retired dealer named were made, in many instances, by Darlot, of Paris. But, from the marking on the mount of yours, it is probable it was made by Coiffier. It is likely to be a good one.

BROMO.—If, as you say, the bromide paper has deteriorated so much in sensitiveness, we should think it was due to the fact of its having been kept, to quote your own words, "in a room where no fire had been during the past winter." Evidently the paper got damp.

BRICK.—Ready-made one-solution developers are useful enough in their way, provided your exposures are uniformly correct. Despite this, however, we question whether many professional photographers employ them; they, no doubt, preferring their reducing agent, alkali and restrainer separate, as each has separate functions to perform.

A. Q. (Napier, N.Z.).—1. The paper has evidently become deteriorated by long keeping, and possibly by the absorption of moisture. We fear there is no remedy. The remedy quoted is only applicable to the kind of paper referred to. 2. The formula is as given by the author. The method of compounding was fully described in the paper published in the JOURNAL.

A. W. W.—A ten-per cent. solution of bichromate of potash is much too strong for sensitising carbon tissue. One of three and a half at this season of the year is quite strong enough. Five per cent., with a short immersion, can be used, but this strength is of no advantage except under very exceptional circumstances. The bichromate of soda is not so suitable as the bichromate of potash.

JOHN HART.—By the time the print reached us it had become so discoloured that it was quite impossible to hazard an opinion as to the cause of the trouble. We surmise, however, that it arises from want of care in sensitising. Avoid dust on the surface of the paper, and see that none is on the solution at the time of floating. Also try a stronger bath—say, sixty grains—and a shorter time of floating.

A. C. H.—For enlarging by either artificial or daylight probably the following method will answer your purpose:—Salt plain paper with sodium chloride, 100 grains; hydrochloric acid, 6 minims; water, 12 ounces. Immerse for 2 or 3 hours, dry, and sensitise on silver nitrate, 1 ounce; citric acid, 8 grains; distilled water, 8 ounces. Dry, expose, and then develop the faint image with pyro, 2 grains; citric acid, 1 grain; water, 1 ounce. Wash, and fix as usual.

T. FRENCH says he has secured a snap-shot of a very important personage. The negative, though very good as a negative on the whole, does not show what might be called a good portrait of the illustrious nobleman, such as one that could be taken in the studio. He has made the picture copyright, and asks how he, being an amateur, can "turn the negative to account," adding that, no doubt, a professional, by retouching, could make the portrait a good one.—All we can suggest is that our correspondent take his negative to some of the publishing houses, and offer it for sale. But, unless it is far better than, from his letter, we surmise it is, we are doubtful if he will meet with much success.

LANCS asks: "What is the practice in London with regard to resittings? Are they given *ad lib.*, or are they charged for, always supposing that the photograph is a good one?"—This is such a purely business matter that we can scarcely offer an opinion. So far as we are aware, there is no rule, and every artist, as a matter of business, consults his own interest. With regard to the question being taken up either by the Photographic Convention or the National Association of Professional Photographers, it certainly does not come within the province of the former, and we doubt whether the latter would care to deal with it, seeing that they could not control the whole trade, even if they could their own members, which is a little doubtful.

H. B. H. writes: "The front of my 7¼×4½ stereoscopic camera is *pierced* for centres of lenses three and a quarter inches apart. Will you kindly tell me at what distance apart should the centres of transparencies be *mounted* so as to see them properly in the stereoscope? To my sight, with three and a quarter lantern plates, they will *not* combine, whereas, with paper prints taken from the same negative, but cut down to two seven-eighths, and one-eighth apart, they *will*. Is there any rule for this?"—In reply: No matter at what distance the lenses of the camera are mounted apart, the centres of the component parts of a stereoscopic picture should not, where possible, be more than two and three-quarter inches apart, and should never exceed three inches. It is quite immaterial how high the picture should be, but in width the limit is restricted. There is no rule that can be adduced beyond this, that the width of the eyes apart is the determining factor by which it is regulated. Hence a pair of lantern slides of standard size could not readily be brought into coalescence by ordinary eyes; we are now assuming, of course, that the ordinary stereoscope is employed. You will find this subject treated with a fair degree of fulness in the editorial article in our ALMANAC for 1877.

A NEW Camera Club has just been formed at Lincoln, and, in proof of its activity, we understand that there is a probability of the fine collection of English photographs recently on view in Brussels being brought, under its auspices, to Lincoln for exhibition there. It will be remembered that a local artist, Mr. R. Slingsby, is one of the exhibitors, and he is taking a foremost part in the endeavour to bring the collection to Lincoln.

LONDON AND PROVINCIAL PHOTOGRAPHIC ASSOCIATION.—April 28, *The New Platinotype Paper*, by Mr. W. H. Smith; demonstration. May 5, Adjourned Discussion on *Wet Collodion*.

PHOTOGRAPHIC CLUB.—April 27, *The Use and Abuse of Yellow Screens in Orthochromatic Photography*. May 4, *Hand Cameras up to Date*. Outing, Saturday next (April 23), Wanstead Park. Train from Liverpool-street at 2.40.

DEATH OF MR. JOHN DUGDALE.—The death has occurred of Mr. John Dugdale, photographer, of 7, The Corridor, Bath. Mr. Dugdale was a native of Lancashire, but went to Bath in 1858, when he commenced business in Broad-street. Shortly afterwards, when opportunity offered, he removed to The Corridor, where his business has been carried on ever since. He was very widely respected, and, although he held no office in the Photographic Society, took a deep interest in its proceedings, and was never happier than when doing something to add to the attractive and interesting nature of its gatherings. As late as March 30 he attended a meeting, and took part in the discussion that followed a paper read by Mr. Appleby. For the last few days he had been unwell, but recently more serious symptoms supervened, to which he succumbed. He was fifty-six years of age, and leaves a widow and three children.

AT the recent Annual Spring Meeting of the Institute of Naval Architects, Mr. A. F. Yarrow read a paper on *Balancing Marine Engines and the Vibration of Vessels*. We learn that one of the most interesting features of the lecture was the photographs of torpedo-boats thrown on the screen by the lantern. The boat was moored in the West India Docks, so as to get still water, and a calm day was chosen. The propeller was removed, so that the engines ran free. The first photograph was taken with the engine in its ordinary condition, no bob-weights being attached. By previous experiment, the number of revolutions that caused the most vibration had been ascertained; 240 per minute was the number, and the engines were run at that speed. The boat was therefore caused to vibrate excessively, and the effect was clearly shown by the waves or ripples thrown off from the side. These were beautifully marked in the photograph, the pattern caused by the intervening wave series being very curious. Many pictures were given illustrating various wave phenomena due to different combinations, one of the most interesting being that in which vibration was caused by one of Mr. Yarrow's assistants springing on the stern 240 times a minute, an athletic feat of no mean order, and one which required considerable training. Another series of photographs taken broadside very clearly showed, by means of the wave motion, the nodes of vibration due to the period, the straight and the broken water-line being well defined.

JOURNAL OF PHOTOGRAPHY.

No. 1669. Vol. XXXIX.—APRIL 29, 1892.

THE NEW CONCENTRIC LENS.

Among the innumerable lenses produced daily in the ateliers of the optician one will search in vain for any in which the application of a new principle of construction is involved. Changes have been rung upon pre-existing discoveries, and improvements, in some cases of great value, have been made, but it is long since any novelty in principle has been imported into the art of lens-manufacture. Happily we are now able to record the advent of one in which a new principle of great practical value has been introduced.

We have on previous occasions spoken of a patent new "concentric" lens of Messrs. Ross & Co., which was being constructed from formulæ by Dr. Hugo Schroeder, the mathematician of the house. Although the patent was completed in 1889, the lens could not be commercially produced before, in consequence of the difficulty of always obtaining the exact qualities of special glass required in its construction. This delay, however, has afforded ample time to test the glass, which, after three years, shows no deterioration.

Notwithstanding our having already given an account of the optical principles involved in, and described the construction of, the lens, we think it well to refer briefly to them again. And first we would observe that, in external appearance, it is nearly identical with the well-known "Portable Symmetrical" of this firm; but, if the lenses be critically examined, it will be found that, while each of those forming the symmetricals has its convex surface of a shorter radius of curvature than its concave surface—a condition of things absolutely necessary in all positive combinations of flint and crown glass—in the "concentrics" the reverse condition prevails, for the concave surface is of shorter radius than the convex. Both surfaces have one common radial centre, and are therefore concentric, hence the name.

Physicists are, of course, well aware that such a condition as that above described could not possibly be fulfilled with the ordinary optical glass formerly at our disposal, because of the flint possessing not only greater dispersion, but also greater refraction, than its crown partner. The construction of a concentric positive lens was, therefore, impossible until the Abbe-Schott glass of Jena was made available. And among the various classes of this new glass were some corresponding to our crown and flint, but in which the former had a higher index of refraction than the latter. The construction of the new lens may be stated thus: It is composed of two similar or symmetrical achromatic combinations, each being formed of two simple lenses, a plano-convex of glass of a high refractive and low dispersive power, cemented to a plano-concave of a lower refracting index, but of the same, or preferably of a higher, dispersive power, these being cemented at the two flat surfaces.

On theoretical grounds, we stated, three years since, that a combination thus formed ought to give such an elongation of the oblique pencils as to yield a flat field with good marginal sharpness; and, now that its commercial production is *un fait accompli*, we have witnessed in the new factory of Messrs. Ross & Co. a series of tests to which it has been subjected, by which this hypothetical conclusion has been fully established.

The demonstration established the fact that the new lens, with an aperture of *f*·20, covered an area of large angular magnitude (over 60° on the base line and about 80° on the diagonal) with great sharpness. The subject tested was a watch dial, the image of which, together with those of an adjoining lamp flame and an artificial star, were examined through a powerful eyepiece from positions both central and oblique to the axis of the lens. To enable this to be effectively accomplished, both the dial and the eyepiece were made to move over a considerable distance at a right angle to the axis of the lens, and observations could thus be, and were, made at various successive stages, representing inches on the ground glass of the camera, from the centre to the side of the field. The definition was uniformly excellent throughout, establishing the fact that not only was the concentric lens anastigmatic, but that it had a perfectly flat field.

How, it may be asked, does the new lens behave when removed into the field and away from the optician's test room—a comparison some might think similar to that as between a laboratory experiment and a manufacture on a large scale? We can reply: Having placed the lens on our own camera and subjected it to the test of landscape experiment, we found, on applying it practically to the reproduction of familiar outdoor scenes containing numerous objects long used as tests, that when focussing the centre of the plate (a 10 × 8 one, the focus of the lens being eight inches), and employing a magnifier of great focal power for the purpose, there was absolutely no difference in definition between the centre and the margin, that the illumination was even, the depth of definition great, and the perfection of the image all that could be desired. The exposed and developed plates resulting affirm this in a lasting form.

Not only for landscape and architectural work but to those who have to make sharp copies of maps and similar cartographic subjects we cannot conceive of anything more perfect, as marginal sharpness is secured without the necessity, hitherto existing, of stopping down to a light-destroying aperture.

The "concentric" must prove a great boon to the photographer who has, with ordinary lenses, to have recourse to very small diaphragms in order to get perfect sharpness at the sides of his picture, more especially if a wide angle of view is included, and we cannot but give it a hearty welcome as a useful addition to our picture-making and copying resources.

We cannot close without bestowing our tribute of praise on

Dr. Schroeder, although praise of such a man, who has so long been recognised as one of the foremost mathematical opticians in the world, is superfluous, and to the firm of Messrs. Ross & Co., to whose enterprise and initiative the introduction of the lens is due.

DEVELOPMENT OF PARTLY PRINTED PROOFS, LANTERN SLIDES, AND OPALS.

Since introducing to the notice of our readers Valenta's method of developing up to full intensity under-printed proofs on collodio and gelatino-chloride emulsion papers a fortnight ago, we have had an opportunity of submitting the plan to practical tests, and are pleased to be able to confirm all that Herr Valenta has said of its efficacy. The growing popularity of printing-out emulsion papers convinces us that the advantage of being able to complete prints as rapidly in dull as in fine weather is likely to find wide appreciation, especially among professionals; and when it is remembered that in this case development does not, as usually understood, mean the conducting of the operation in the dark room, but that it may be performed in subdued or shaded daylight, one of the drawbacks inseparable from all development processes is removed.

New processes and modifications of old methods not infrequently dismay the photographer by involving the employment of specially prepared developers and other solutions differing from those in common employment—a natural reluctance to undertake the trouble of arranging the preliminaries often lying at the bottom of the neglect and coldness with which novel processes are at the outset generally received. In the present case, however, though Herr Valenta directs the use of an acid instead of an alkaline developer, a glance at its composition (see page 248, *ante*) will assure the photographer that, in all probability, he will have it among his preparations, practically ready mixed and only awaiting dilution. In our own case, we employed a stock solution, which we very frequently use for negative purposes, as the basis of the developer.

In taking prints on two English emulsion papers, samples of which we happened to have by us, we were careful to remove the pictures from the frames so soon as the deep shadows and a faint impression of the half-tones were visible—the prints having a complete absence of details, and, indeed, being but very faint impressions produced by an exposure of about two minutes in diffused sunlight. They were treated with a developer made up, from a stock solution, in the following proportions:—

Pyro	5 parts.
Soda sulphite	25 „
Citric acid	10 „
Water	1000 „

The pyro and sulphite were, of course, taken from the stock solution, the citric acid being added after dilution.

In this solution development was from four to five minutes in starting, and then the weak, purplish pictures gradually acquired a sepia tint, which next developed into a positive brown shade, and then, growing in depth and vigour, gradually passed into a most rich, heavy purple colour, the whole operation lasting perhaps ten minutes. By the time the latter stage was reached, the whites, of course, were so considerably degraded as to render the prints useless, but in the ordinary method of working, development would be stopped long before this stage was reached. For subsequent toning in a combined toning and fixing bath, we afterwards found that the stage at which development should be stopped and the print washed, was when the image had acquired the decided brown tone of which we have spoken.

The chief element of success in the method, however, struck us as being the wonderful degree of power which the developer possesses over the qualitative character of these weakly printed images. Not only does it build up the shadows to full intensity, and render the scale of tones as completely as if the full print had been taken in the frame, but it brings out the utmost fineness and delicacy of detail without setting up coarseness or granularity. Moreover, it must not be imagined that the developer only acts on those parts of the picture where the faint impression visible to the eye has been formed; on the contrary, it brings out a considerable part of the image which is invisible, thus fulfilling the functions of a developer of the latent image in the ordinary sense. Indeed, we believe that eventually this paper will be susceptible of exposure in the printing frame in the usual way without the necessity of any part of the image being visible before development; and hence considerable rapidity of working will be assured. We are experimenting in this direction, and at some future date will describe the results.

Continuing his attempts with developing weakly printed images on printing-out surfaces, Herr Valenta, as will be seen from his communication in our present number, describes the application of acid developers to the development of faint images on glass for lantern slide, opal, and transparency work. The comparatively small extent to which printing-out surfaces for these kinds of work are employed in this country does not render the application so valuable as in the analogous case of paper prints, but possibly it may lead to a greater practice of the plan recommended by Valenta. We shall recur to the subject.

ON SPOTTING.*

Regarding the treatment of the negative itself, we might be expected to write upon the use of the knife, an operation now of great importance; but, to avoid our brief comments developing into a treatise upon the methods of retouching, their scope must preclude more than a brief allusion to such work. It is carried out both by the knife and the needle, some being more expert with one than the other. We may say that a specially made knife, advertised for some time past in the business portions of this Journal, has been in our hands most successful, taking the place of both needle and knife, one end being sharp, and the other more scoop-like. When spots have been removed by one or the other means, the surface is apt to become too uneven to work upon readily with the brush for final smoothing, and here the employment of Indian ink will be found very valuable, our warning to avoid using saliva to moisten brush or colour being remembered. Let it also be well borne in mind that, when more than a single print or two is required, it is far better to do as much of the work on the negative as possible. It is true a retoucher's labour is far better paid than a spotter's; but a very little time spent upon a negative may, in the aggregate, prevent loss of the labour of the spotter upon the prints.

Coming now to the spotting of the prints themselves, the ground is more familiar, for there are few who have not, at one time or another, to remedy defects of the kind.

* Concluded from page 241.

We may say that there are many instances where unnecessary work is made for the spotter. We allude to dirty negatives. In the course of printing a number of copies, it is almost inevitable that particles of dust and foreign matter generally fall upon the varnish, and have an unpleasant knack of adhering. The use, therefore, of a fairly stiff brush to "sweep" the negative each time a fresh piece of paper is filled in should be an imperative rule in all printing operations.

The usual way of removing white or ·ht spots is to stipple upon them in water colours of the exac ·nt of the print. This is too often carelessly done, the resul ·oeing that, through imperfect matching, the stippling becomes quite prominent. Often is this caused by the stippler mixing a batch of colour, and using the same pigment for all shades of colour in the prints. Such carelessness should not be permitted. A stock mixture may be made, and allowed to dry, for use as required, upon the palette, but it should be modified by the addition of colder or warmer colours, as the tint of the print may indicate. A common mixture is Indian ink, indigo, and crimson lake. Madder brown is used also by many, and forms a useful basis; but we would here interpose a word as to the fugacity of the pigments used. It is true that many prints fade before any alteration of the spotting, but not always is this so; and it should be the aim of every upright photographer to make every part of his work permanent. To this end, we say eschew crimson lake; it is bound to give way. The madders are better, but uncertain. For setting the palette, our recommendation is to take the new alizarine crimson, indigo, Indian ink, and Vandyke brown. There need then be no fear as to the pigments ever giving way, even if used on permanent prints. When the colours are used on platinotypes or other unglazed surfaces, the colours as found in the colour-box will be suitable; but, when albumenised prints are to be spotted, it will be found necessary to use a very copious addition of solution of gum arabic. Without this precaution the pigment will dry with a dead surface, and greatly mar the effect of the finished print. To the inexperienced it will be surprising what a large amount of gum is needed; and, the deeper the colour, the more the gum has to be increased.

The greatest trouble will be experienced when endeavouring to spot out dark spots. As a matter of fact, there should not be any such to remove, for the negative itself should be first treated, and all marks of this kind removed. If, however, it be desired to remove any marks of the kind, the only plan—a makeshift at the best—is to use Chinese white. But it will be found necessary to mix it on quite a different principle to the dark colour. The plain white is inadmissible, it dries up to such a cold tone. It will be found that there must be added to it a red—light red or alizarine crimson, or both—till upon the palette it appears quite pink. For platinotypes and other similar surfaces, coloured chalks will be better than water-colour for opaque colour, and, indeed, some photographers use them for dark spotting also, to the entire exclusion of water-colour pigments.

We have now covered the entire ground, and, if we have left untouched any difficulties that have been experienced but not surmounted by others, we shall be glad to supplement our remarks by information in the usual column for correspondents.

Illegal Photographs.—Evidently the traffic in indecent photographs, like that in photographic piracies of works of art, is not yet suppressed. Last week two persons were committed for trial, and a third remanded, for dealing with the former. Photographic copies of some of the most popular engravings are freely hawked about the streets. The difficulty encountered in stopping this class of work is that of reaching those who produce the negatives. Usually the prints pass through several hands before they get to the retailer.

The Zeiss Lenses.—In reference to the Zeiss Anastigmat lenses, it may be of interest to point out that Messrs. Ross & Co. are among the few licensees of the firm of Messrs. Carl Zeiss & Co., of Jena, holding authority to manufacture the lenses in accordance with the terms of the patent. It will be remembered that the number of the licensees is limited; Messrs. Ross's rights of manufacture extend over the British empire, they being thus the only English house licensed. We understand that they will shortly place several of the Zeiss series of Anastigmats on the market.

Death of an Astronomer.—Every one will hear with regret the sad and fatal accident that befell Mr. John Hartnup, the well-known astronomer, at Bidston-hill Observatory, one day last week. While the unfortunate gentleman was examining some meteorological instruments at the summit of the building he overbalanced himself and fell to the ground below. Death was instantaneous. Mr. Hartnup had a wide reputation as a scientist, particularly in connexion with meteorology. He and his father had been connected with the Bidston-hill Observatory for nearly half a century.

Indian and Colonial Slides.—The set of Indian and Colonial slides now going the round of the Societies affiliated to the Photographic Society of Great Britain are, both topographically and photographically, of the highest interest. We can imagine that photographic societies in the Colonies and India would give as hearty a welcome to a good selection of slides of home scenery as that which has been extended to these Cape, Tasmanian, and Indian pictures. It would be a graceful way of returning the compliment, and we hope that the matter will be taken in hand by the Affiliation Committee, as we are confident several good sets might be made up from the contributions of the various Societies.

An Old Process.—Photo-typographic blocks are rapidly ousting wood engravings from the field for illustrative purposes. The majority of the blocks are produced by spreading a thin coating of bitumen on a metal plate, exposing it to light under a *cliché*, dissolving away the unaltered portions with a suitable solvent, and then etching the bare parts with an acid, leaving the others in relief to form the printing surface. Now, it does not seem to be generally known that this was precisely what was done by M. Niepce just sixty-five years ago. He coated a metal plate with a solution of bitumen in oil of lavender, and exposed it to light either in the camera or by super-position. The image was then developed with a mixture of oil of lavender and benzol. The plate was afterwards bitten in with acid.

The Convention.—It will be seen by a letter from Mr. Combrano, the Honorary Secretary of the Photographic Convention of the United Kingdom, which we print elsewhere, that even thus early papers by such excellent men as Bothamley, Robinson, and Pringle have been promised for the Edinburgh meeting, while Miss C. W. Barnes is also on the list for a subject of which she should have the best possible opportunities of arriving at a good idea. Looking at the fact that the gathering is largely of a holiday character, and that a great deal of matter has to be digested within a little time, may we humbly hope that the authors of papers will remember the relationship which brevity bears to wit? In former years there have been some good papers at the Convention, but the length of some of them was in precise proportion to their value.

The Half-holiday Movement.—Reverting to the announcement we made last week, that all the leading photographers in

Glasgow had agreed to close their businesses for half a day in each week in order to give their *employés* a holiday, it seems a little strange that the whole of them do not close on the same day of the week. As it is, some will be open while others are closed, and this may possibly lead to business that would have gone to one establishment that is closed going to another that happens to be open. Of course our Glasgow friends know their own business best, and doubtless they have a good reason for their present arrangement; but to many it seems anomalous that the day for closing was not made universal throughout the town. However, the assistants are to be congratulated; and, as we said before, we hope other towns will quickly follow suit, including our great metropolis.

An Innovation.—It is so difficult to get up anything in the shape of a novelty at the meetings of Societies nowadays that a little incident which occurred at the South London Photographic Society the other night appears to us to have all the charm of originality about it, and, being original may, perhaps, lead to imitation. It appears that the Chairman demonstrated the new cold-bath platinum printing process, and at the conclusion of the demonstration a number of, no doubt, very excellent prints remained. Probably the Chairman had no further use for these prints—did not wish to take them away with him, or did not want them, it is hard to tell which. At any rate, in his dilemma, he put them up for sale, the result being that they realised a sum of 3*l.*, which was swept into the coffers of the club. We have heard it said that photographic societies are being rapidly turned into mere advertising mediums; now it seems they are becoming vehicles for trading.

Process Blocks and Photogravures.—It would seem, from an article that we reprinted from *Anthony's Bulletin* in our previous issue, that, in America, impressions from phototypic half-tone blocks were being foisted upon the public as photogravures, inasmuch as the writer points out very clearly how the one may be distinguished from the other. We are free to admit that "process blocks" are made to great perfection in the States, but we have seen none—and we have seen some of the very best—that would for a moment, in this country, be mistaken for a photogravure, that is an impression from an intaglio plate, even by the most casual purchaser. There is a depth, richness, and perfect gradation in an intaglio, photographically engraved, plate, that at present cannot be equalled in a typographic block however skilfully produced. The writer mentions that, with a process block, an office boy can "kick off" a thousand impressions a day, but an experienced intaglio printer cannot produce above two hundred good ones per diem. As a matter of fact, we may say that with some of the large intaglio plates now produced on the Continent not more than twenty or thirty impressions a day are made, so much care and attention is devoted by the printer to the inking in and wiping out of the plate in order to secure the excellent results that are issued.

Processes before their Time.—In connexion with the above subject it may be mentioned that the method of breaking up the tones of a subject into lines or dots to obtain a printing plate was first practised and patented by Fox Talbot forty years ago. He, about the same time, produced intaglio plates by etching through an exposed bichromated film, a granular surface being obtained by a powdered resin. Practically, this is the method now almost universally employed for "photogravure." Some of Talbot's work will still hold its own against many untouched plates of the present day. Half-tone surface blocks, and good ones too, were produced by Pretch in 1855, and as far back as 1866 Bullock Bros. produced photo-lithographs in half-tone that were quite equal to those now made. Hence it will be seen all that is now being done was done many years ago. This being the case, it may justly be asked why all these processes lay dormant so long. The only answer is, that they were introduced before their time. Their value was not recognised, and they were not therefore appreciated. These are not the only processes in connexion with photography that have been introduced too soon, and afterwards reintroduced later on with success.

A Novel Glass House.—"Those who live in glass houses should not throw stones," says an old aphorism. But who would wish to live in a glass house, if it be of the type of some photographic studios, it is difficult to conceive. However, a glass dwelling may possibly be made comfortable. According to an evening contemporary, the King of Siam has had a pavilion built of glass; walls, floors, and ceilings are of slabs of glass, the joints being made with an impermeable cement. The door is made to close hermetically. The roof, we are told, is provided with ventilators in tall pipes. The building stands in a large reservoir, and becomes submerged in water by opening a sluice at the side of the latter. In this transparent edifice the King is said to find a perfectly cool habitation in which he spends a great portion of his time. If the thing be true, this is certainly a novelty in glass houses, and must be in strong contrast to those generally used for photographic purposes in hot weather. By the way, it is somewhat surprising that so little is done in artificially cooling studios during the summer months. If a pipe perforated with small holes, and connected with the water supply, were fixed along the ridge of the building, a number of fine streams could be made to trickle down its roof and sides. This would keep the studio pleasantly cool even in the hottest weather, and thereby often conduce to more pleasing portraits. Some studios we know are thus provided, but their number is very limited.

THE CHEMICAL CHANGES ATTENDING PHOTOGRAPHIC OPERATIONS.

I.—The Theory of Development in relation to the Essentially Electrolytic Character of the Phenomena and the Nature of the Photographic Image.

[Camera Club Journal.]

No pretension to be even a professional amateur photographer is made by the writer of these lines. At intervals extending over a considerable period he has exposed and developed plates in a conventional and rule-of-thumb manner, but about a couple of years ago an awakening of his photographic conscience took place, and he began to ask himself whether he had any true understanding of what he was doing. Finding that he had not, and that the text-books afforded but cold comfort, he bethought him that he was working in a manner utterly unworthy of a member of that fraternity which seeks to give its meaning to the watchword by which it is led—Science: "Knowledge co-ordinated, systematised, and arranged."

To-night he will attempt but a very general confession of the faith that is beginning to arise within him after much pondering over photographic literature, and after a couple of years of study and experience of the behaviour on development of plates exposed in the field at all seasons, and under a considerable variety of conditions, one chief object in view having been to arrive at the explanation of the controlling influence exercised by the restrainer, and the accelerating effect of alkali.

Thus much by way of preface. A prologue may be added to facilitate the explanation of points of fundamental importance.

In the year 1868 De la Rue and Müller described a new form of voltaic cell, consisting of a cylinder of silver chloride cast around a silver wire as negative element, opposed to a zinc rod as positive element, placed side by side in a tube containing a solution of a chloride, ammonium chloride being that ultimately preferred. [It is worth while noting that they speak of silver chloride as so poor a conductor of electricity that it may be regarded as an insulator, and that on this account it is necessary that the silver wire around which the chloride is cast should project through it into the solution. On the other hand, it is also noteworthy that even solid silver chloride may be electrolysed, and that directly its temperature is raised sufficiently to make it viscous, it is an exceedingly good conductor.] In such a cell the silver chloride remains unchanged until the circuit is completed, by joining the zinc and the silver by a conductor of electricity; immediately this is done a current passes, and simultaneously zinc dissolves, and silver chloride becomes deprived of chlorine. Although ammonium chloride is used in the cell, in considering the nature of the interchanges, it is permissible to assume that hydrogen chloride—one of the constituents of ammonium chloride—is the active agent; for, as will be shown later on, at the same time that hydrogen chloride is being withdrawn from ammonium-chloride and used up, hydrogen chloride is being produced and converted into ammonium chloride, and, as the two actions balance each other, it is unnecessary to consider them.

Supposing that silver, and not silver coated with silver chloride, were opposed to the zinc in the cell, the latter would dissolve as chloride, but hydrogen would be given off at the surface of the silver. In this case the current would rapidly fall off, the cell would become *polarised*, in consequence of back action setting in between the hydrogen coating the silver and the zinc chloride, which would lose chlorine. As it is reversible, the change occurring under such conditions may be written—

$$Zn + 2\,HCl \rightleftharpoons Zn\,Cl_2 + H_2$$

i.e., the equation may be read either backwards or forwards. In the

presence of silver chloride in contact with the silver, this back action or polarisation is prevented, no hydrogen ever being set free, as at the same time that the zinc combines with chlorine from the solution an equivalent amount of hydrogen combines with chlorine of the silver chloride, and thus the amount of chlorine as ammonium chloride in solution is maintained constant. We, therefore, may represent the state of affairs in the cell before and after the current passes in the following manner:—

Zinc plate	ClH	ClAg	Silver plate
	ClH	ClAg	

Cell at Rest.

$$= \text{Zinc plate} \;|\; Zn\begin{matrix}Cl\\Cl\end{matrix} \;|\; \begin{matrix}HCl\\HCl\end{matrix} \;|\; \begin{matrix}Ag\\Ag\end{matrix}\left\{\begin{matrix}\text{silver}\\\text{plate}\end{matrix}\right.$$

Cell in Action.

The electrical pressure developed in such a cell—its electromotive force, or E.M.F.—is about 1·05 volt; the theoretical value may be calculated in the following manner:—

It is known from thermo-chemical measurements that the dissolution in dilute muriatic acid (HCl : H_2O = 1 : 200) of sufficient zinc to displace two grammes of hydrogen would involve the evolution of 34,200 gramme-deg. C.-units of heat.

If this amount of hydrogen and the equivalent amount of chlorine were to interact, and form hydrogen chloride, 78,640 units of heat would be liberated; while by the interaction of the equivalent amounts of silver (216 grammes) and chlorine, only 58,760 units of heat would be liberated. Consequently, 78,640 − 58,760 = 19,880 units of heat would be developed if the hydrogen, instead of being liberated, were to reduce silver chloride, and the total heat evolution resulting from the conversion of the zinc into chloride at the expense of the chlorine withdrawn from the silver chloride would be 19,880 + 34,200 = 54,080 units. The corresponding E.M.F. is found by dividing by 46,000, a constant which need not be explained here; hence—

$$\frac{54{,}080}{46{,}000} = 1{\cdot}18 \text{ volt.}$$

The difference between this and the observed value is attributable to the fact that the conditions for which the calculation is made are not precisely those which obtain in an actual cell; probably the zinc chloride is not fully hydrated in the electrical circuit, and the heat of formation of some less hydrated chloride should be taken for the purpose of the calculation.

The extent to which electrolysis of silver and hydrogen chloride takes place, *i.e.*, the amount of zinc dissolving and of silver chloride reduced in the cell depends on the resistance in the electrical circuit, since—

$$C = \frac{E}{R}$$

where C stands for current, E for electro-motive force, and R for resistance. This is the well-known *Ohm's Law*; its importance in connexion with photographic phenomena has been strangely overlooked.

To apply this law to chemical changes, it has merely to be borne in mind that C may also be taken as meaning amount of chemical change, and it is scarcely necessary to point out that the most exact method of measuring an electrical current consists in determining the amount of chemical change which the current produces, by weighing the deposit of silver obtained on passing it through a silver nitrate solution. E, as before, is the electromotive force corresponding to the interchange, and R the resistance, not of the liquid as a whole, however, but of the circuit within which the interchange is effected, which may be quite a different thing, and unfortunately at present is beyond measurement.

It will be noted that the E.M.F. of the silver chloride cell is the sum of two E.M.F.s, the one developed in the formation of zinc chloride from zinc and hydrogen chloride, the other in the reduction of silver chloride. In any case, in order that action may occur, it is essential that the change, on the whole, be one in which energy is set free; but this is not necessarily the case in all parts of the change when it is resolvable into parts. This is a consideration of primary importance in connexion with the theory of development, and may be illustrated by the following examples:—Zinc readily dissolves in diluted sulphuric acid, if coupled with a less positive conductor. Copper, however, does not, even if the acid be boiled; but copper dissolves readily enough if oxygen be passed into the heated diluted acid. Thermo-chemical measurement shows that, while the dissolution of sufficient zinc to displace two grammes of hydrogen from sulphuric acid is attended with a liberation of energy expressed by the number 37,730 if represented in heat units, the dissolution of the equivalent amount of copper could only take place if energy were supplied to the extent of 12,400 heat units; but, as oxygen and hydrogen interact, forming water, with liberation of energy to the extent, measured in heat units, of no less than 68,360 units per two grammes of hydrogen, it becomes possible for copper to dissolve in sulphuric acid, in presence of oxygen in a circuit containing copper, sulphuric acid and oxygen, with development of energy equal to 68,360 − 37,730 = 30,630 heat units: *i.e.*, a positive E.M.F. is developed in such a circuit.

In the old collodion wet-plate process development was effected by means of silver nitrate left adhering to the plate on removal from the silver bath, and a reducing agent such as ferrous sulphate duly restrained by, say, acetic acid. When solutions of ferrous sulphate and silver nitrate are mixed, unless very dilute, a precipitate of silver is soon formed, but the amount precipitated always falls far short of the total amount of silver present, as the interaction is reversible.

$$\underset{\text{Ferrous Salt.}}{2FeSO_4} + 2NO_3AG \rightleftharpoons \underset{\text{Ferric Salt.}}{Fe_2(SO_4)_3(NO_3)_2} + 2Ag.$$

The extent to which silver is deposited depends on the proportions used the concentration, and the temperature; if the solution be sufficiently dilute and acid be present, no precipitation occurs. The exact function of the acid is not clearly determined, but probably in its presence atmospheric oxygen intervenes, and, by acting in conjunction with it and ferrous salt, further promotes the dissolution of the silver, thus rendering reversal complete, *i.e.*, no chemical change is apparent. There can be no doubt that in the liquid the interchanges thus pictured occur within voltaic circuits, and that, as no action is observed when acid is present, the algebraic sum of the currents in all these circuits is *nil*. It is to be supposed that on covering an exposed plate with such a solution the image acts like the silver rod in the De la Rue-Müller cell, silver nitrate taking the place of the silver chloride, and ferrous sulphate that of the zinc rod in the cell; hence the silver is necessarily deposited on the image.

The growth of the image in silver therefore takes place mainly upwards into the solution in the case of a collodion wet plate, and only to a minor extent within the film; it appears probable that the silver haloid particles in the film in contact with the image are but little, if at all, affected, owing to the superior readiness with which silver nitrate is reduced, and the "weakness" of the developers used. It is very noteworthy that, owing to the absence from collodion of "active impurities," its use affords little or no opportunity for the occurrence of changes at points where light has had no action on the film, hence the brilliancy and sharpness of wet collodion pictures.

In considering the alkaline development process of modern gelatine dry-plate photography, it would appear to be necessary to distinguish between methods in which the *alkaloid* ammonia and those in which alkalies, either caustic or carbonated, are used. Even silver bromide is appreciably soluble in ammonia; consequently, in developing with the aid of ammonia, the image is in part formed from silver in solution. The extent to which this takes place depends chiefly on the amount of bromide added as restrainer, one result of adding this restrainer being to precipitate the dissolved silver haloid, or rather to prevent its dissolution by the ammonia. Probably it is to this peculiarity that the marked difference in results obtained by using ammonia and pyro is, at least in large part, attributable; and the same circumstance would favour the formation of an image not wholly composed of silver, *i.e.*, of a species of pigment.

All who have worked with pyro and ammonia know that the picture has properties which distinguish it from those obtained with developers in which ammonia is not used, and that the liability to certain peculiar kinds of fog is special to ammonia developers; this is probably attributable to the conjoint action of the dissolved silver and colouring matter formed by oxidation of the developer.

When alkalies are used, the image grows at the expense of the solid silver haloid with which it is in contact, just as the silver wire in the De la Rue-Müller cell grows at the expense of the silver chloride cast around it. The various developers used, like zinc, are all oxidisable substances; and, just as the zinc by combining with chlorine enables the hydrogen of hydrogen chloride to withdraw chlorine from silver chloride attached to the silver wire in the cell, so the developer, by laying hold of the oxygen of water, enables its hydrogen to withdraw bromine from the silver bromide attached to the image on the photographic plate which has been exposed to light. Taking quinol (hydroquinone) as the type, the interaction may be expressed thus:—

Latent image	AgBr AgBr	$\begin{matrix}H\\H\end{matrix}O$	$\begin{matrix}H\\H\end{matrix}C_6H_4O_2$
	Silver Bromide.	Water.	Quinol.

$\rightleftharpoons$

Before Development.

Latent image	Ag Ag	BrH BrH	$O\begin{matrix}H\\H\end{matrix}$	$C_6H_4O_2$
		Hydrogen Bromide.	Water.	Quinone.

After Development.

Viewing the process in this manner, the function of the alkali would seem to be to neutralise the acid as it is formed, or rather, to prevent acid ever being formed, thereby preventing a reversal of the interaction which otherwise would take place, owing to the attraction of silver for bromine and of quinone for hydrogen, *on which account the equation given above is written as expressing a reversible change.*

But the remarkable positive influence of alkali in hastening development, and the retarding influence of a bromide, such as potassium bromide, are in no way accounted for in the foregoing explanation.

As regards the alkali, its influence is probably, at least in the main, due to the fact that a silver haloid in presence of alkali and a reducing agent tends to undergo reduction, the metal of the alkali forming a compound with the halogen, while the oxygen of the alkali forms water with th hydrogen of the developer. One of the products of this interchange i the alkali-metal haloid, *and, the interchange being a reversible one,* its re

versal is promoted by the presence of added bromide, and consequently less silver is deposited when the restrainer is present, thus:—

$$\text{Image} \left|\begin{matrix}\text{AgBr}\\ \text{AgBr}\end{matrix}\right| \begin{matrix}\text{KOH}\\ \text{KOH}\end{matrix} \left|\begin{matrix}\text{H}\\ \text{H}\end{matrix}\right.\text{C}_6\text{H}_4\text{O}_2 \rightleftharpoons$$

Alkali.

$$\text{Image} \left|\begin{matrix}\text{Ag}\\ \text{Ag}\end{matrix}\right| \begin{matrix}\text{BrK}\\ \text{BrK}\end{matrix} \left|\begin{matrix}\text{OH}_2\\ \text{OH}_2\end{matrix}\right| \text{C}_6\text{H}_4\text{O}_2$$

Provided it be assumed that the latent image is capable of acting in a manner corresponding to that in which the silver rod acts in the silver chloride cell, it is unnecessary to take its precise character into account. Yet, to fully understand the relative importance of the various factors operating during exposure and development, it is necessary also to consider the nature of the photographic image. For an able statement and discussion of this and of very many other photographic problems, reference may be made to Meldola's *Chemistry of Photography* (Macmillan & Co.).

It is now generally admitted, Meldola says, that the invisible image is of the same composition as the darkened product of photo-decomposition of a silver haloid, and he inclines to the belief that this darkened product is an oxyhaloid compound of silver.

Mr. H. B. Baker, whose name is familiar to chemists through his remarkable observations on the incombustibility of carbon and phosphorus in dried oxygen, has for some time past been studying this subject with special care, and it may be here stated, on his authority, that when darkened silver chloride is treated with chlorine it gives off oxygen, and that water is formed when it is heated in dried hydrogen; these observations clearly indicate that the darkened substance contains an oxidation product, and confirm Hodgkinson's results, to which Meldola has drawn attention.

But, if the arguments adduced in favour of the view that the invisible image is of the same nature as the darkened product be carefully examined, it will be found that they are by no means cogent. One object of this communication is to suggest that probably they are not; and, further, that in an ordinary photograph there are perhaps two distinct latent images behaving differently on development, which may be conveniently spoken of as the *blue* and the *yellow* image. It is contended that the blue image is silver, and only the yellow a silver oxyhaloid. The action of light on silver haloids is apparently strictly comparable with that of an electric current—it is *electrolytic;* moreover, the effect of light would seem to be that of a very high electromotive force, and it would therefore overcome great resistance. It may be supposed that when exposed to the mis-called actinic rays—those at the blue end of the spectrum—in contact with a substance capable of appropriating bromine, *i.e.*, a depolariser, such as gelatine and the products formed therefrom during ripening, silver bromide has its silver liberated. The development of the image thus formed has already been described; such an image would be the absolute counterpart of the silver wire in the De la Rue-Müller cell.

Lower down in the spectrum, in the yellow region, the silver bromide apparently undergoes electrolysis in some occult manner in a circuit which includes oxygen, and, while losing some of its bromine, takes up oxygen in place thereof.

In anticipation of the objection that if these two actions take place darkened silver haloid should contain both silver and silver oxyhaloid, and that apparently the former is not present in it, let it be remembered that, when a moist silver haloid is affected by light, the halogen liberated in the formation of the oxyhaloid will attack the silver which it is here supposed results from the decomposition of the haloid by the blue rays, and will convert it into silver haloid. In a gelatine plate, however, halogen is taken up by the gelatine, &c., and thus the silver would be more or less protected; after a time, the gelatine having become saturated, the silver would tend more and more to become re-halogenised; in fact, it would entirely depend on the length of exposure whether the image consisted of silver and silver oxyhaloid, or only of the latter.

On developing what is known as an over-exposed plate, which presumably is rich in oxyhaloid, the image apparently behaves very differently, according as only alkali is used in conjunction with the developer, or alkali and a bromide. It would seem probable that a silver oxyhaloid would resemble silver oxide in being very unstable, and that, in contact with alkali and a reducing agent, it would become resolved into silver haloid and silver, thus affording an image in silver, the growth of which, on continuing development, would occur in the manner previously explained. The decomposition of the oxyhaloid, like the change which occurs when solutions of silver nitrate and ferrous sulphate are mixed, would take place, so to speak, with a rush, and the image grows so rapidly that the picture would flash into view. One function of the restrainer is to prevent this sudden change; it would seem that under the conjoint influence of a bromide, alkali, and a reducing agent, the silver oxyhaloid is converted into silver haloid. The extent to which this change takes place, and the rate at which the picture gains in strength, would depend on the amount of bromide present, the relation which obtains between the amounts present of the several substances which act conjointly, the concentration, and the temperature; consequently the picture might, as is the case, be caused to grow at any desired rate.

In a gelatine plate there are always present substances tending to interact with the silver haloid in presence of alkali much in the manner in which silver nitrate and ferrous sulphate interact, and which promote the occurrence of the reduction of the haloid by the alkali and the developer already referred to. Such substances are kept under control by the addition of the restrainer. If, therefore, the development of an over-exposed picture be continued, fog is necessarily produced unless sufficient bromide be added to check the action of the reducing substances in the gelatine. For a similar reason it is desirable to use weak developers with plates which have had a very brief exposure. In such a case the image is so very faint that the difference between the unexposed and exposed portions of the plate is but slight—the value of R in the equation—

$$C = \frac{E}{R}$$

is very nearly the same in the two sets of circuits. By using a developer which has no appreciable action on the unexposed plate, the latent image is slowly strengthened, and ultimately R is so much diminished that it becomes safe to use a stronger developer.

The development of pressure marks may be explained from the same point of view. Clearly there would be a diminution of resistance in the lines of pressure, and hence, on application of the developer, circuits would be formed within the film in these lines, in which action would take place more readily than in the uncompressed parts.

Reversal by means of *thiourea*, with which we have been made familiar by Waterhouse, may also be referred to here. If it be supposed that the latent image is converted into a sulphur compound which is not developable, the action would be confined to the unexposed parts of the film, which, sooner or later, always give way under the influence of alkaline developers. Complete reversal would thus be secured.

With reference to the sensitiveness of plates, the explanation at the end of the "prologue" of the influence oxygen exercises in promoting the dissolution of copper in diluted sulphuric acid is apposite. The sensitiser promotes the action of light in a precisely similar manner, it may be supposed; and it is clear that any degree of sensitiveness may be secured, according as the substance associated with the silver haloid, and which acts as depolariser by combining with the halogen thrown off from the haloid under the influence of light, is capable of contributing more or less of the energy necessary to render the interchange one which would occur without any external E.M.F. being brought to bear.

Judged from the point of view here advocated, it would seem that there can be but very little difference between various developers when used under comparable conditions; at most the variation would arise in the rate at which development would take place. It does not appear probable that the character of the deposit would vary greatly in "grain" or colour. But, since in practice considerable differences are noticed, it is probable that not only in the case of pyro and ammonia, but also in others, the deposit does not invariably consist of silver alone.

In concluding this statement, attention may be called to the great opportunity for research of a by no means difficult character which photography affords. We want experiments made in a great variety of directions, but under much simpler conditions than heretofore adopted; the effects of monochromatic lights, and the influence of various pure substances as sensitisers in association with silver haloids, are especially important subjects to study.

Abney has shown that such a substance as a nitrate stops the action of the yellow rays; we want observations on the effect of such substances. Gelatine plates have been of great service to picture-makers, but they are a great bar to scientific progress, as we can never know their exact composition, and we must return to the neutral medium collodion if we wish to gain definite information on matters such as have been referred to. Such experiments, moreover, should have great practical value, as the results may ultimately enable us to largely extend the applications of photography.

HENRY E. ARMSTRONG, F.R.S.

AMERICAN NOTES AND NEWS.

For the Poor Amateur.—Our sprightly young contemporary, the *Pacific Coast Photographer*, says it has received ten dollars from a kind, benevolent lady to be applied on account of six subscriptions to the *P. C. P.* for "poor amateurs!" It says that, if there are any amateur photographers who find themselves unable to subscribe to their journal from lack of means, they will be pleased to send it to them. We compliment our contemporary on its ingenuity in advertising.

Oxalic Acid as a Preservative of Pyro.—Mr. W. E. Partridge, in the *American Amateur Photographer*, enters a plea for this "long-forgotten acid" as a preservative of pyro. It is permanent, and, used in small quantities, keeps the solution as clear and colourless as water. He recommends employing it in the proportion of two per cent. of the water in which the pyro is to be dissolved; for hot-weather work, three per cent.; at the latter strength he speaks well

of it as a preservative of hydroquinone, which, in the solid state, does not, as a rule, keep well.

Keeping Properties of Sulpho-Pyrogallol.—In an address to the Albany Camera Club, Mr. F. C. Beach says that, in 1882, he imported two bottles of the late Mr. Herbert B. Berkeley's sulpho-pyrogallol, one of which he has kept to this day. It is still clear. It is a ten per cent. solution, forty-eight grains of pyro to the ounce. Though standing so long, the colour of the solution has changed very little. It is of a light brown hue, and Mr. Beach believes it will be as vigorous as ever. Mr. Berkeley acidified the neutral sodium sulphite with citric acid, and then added the pyro.

The Camera and Disease.—Dr. M. L. Vander Straker, of Kansas, says that the latest novelty in the way of photography is the employment of the camera at hospitals to register the modifications of disease. Different proofs are taken at various stages of the disease, and the comparison of these with photographs of others similarly afflicted discloses phenomena of great interest and value to medical science. The employment of the camera in this manner on this side of the Atlantic is no novelty, and we are aware of doctors who have photographed their patients both before and after their cure, to show them the beneficial effects of their treatment. If the results are sufficiently striking, what better testimonial or recommendation could a doctor require?

The Californian Camera Club, San Francisco.—Since the organization of the Club a little over two years ago, it has made great strides. The Club is now established in commodious quarters in one of the handsomest buildings in the city, and has come to be recognised as one of the leading photographic societies in America. Its dark rooms are at the disposal of accredited visitors, and the members extend a special invitation to the members of sister societies—American and "foreign." Meetings, first Tuesday of each month; "Club Talks," every Wednesday; "Outings," first and third Sundays from April to November; Monthly Exhibitions, date set by Committee. Outings on Sundays! Oh, fie, good Californian clubbers!

"1992."—Mr. Bogardus amused us the other day when he looked backwards, and told us a few of the funny things which occurred in photography years ago. Now he has reversed the process, and, in the pages of the *St. Louis and Canadian Photographer*, has been putting on the cap of prophecy. In 1992 all photographers are obliged to take out a licence, and may not photograph more than three babies a minute. Cyanide, inserted in a funnel in the throat of the victim, is used for executions, as more economical than electricity. Photographs are all taken in natural colours; ladies complain that their cheeks and lips are not red enough, and red-nosed men say their noses are not as red as the pictures make them. A Convention, to which members proceed on flying machines, is held, 25,000 members being present. After considerable speechifying, it adjourns to April 1, 2042, it being held once in fifty years.

American Silver Printing.—At the last meeting of the London and Provincial Photographic Association Mr. H. Snowden Ward, who had just returned from a brief visit to America, passed some rather severe strictures on the qualities of American professional photographic printing which has caused us very great surprise. If these strictures are justified, the character of the printing turned out by our transatlantic friends must have undergone a change for the worse, as from our experience of it we are by no means disposed to place it, either on technical or artistic grounds, one single point below English silver printing of the highest class. As for the permanency of American albumen prints, the mass of evidence is in favour of its being as great as that produced elsewhere. Of course we here speak of the matter in a general sense, as we presume did the critic we have quoted. It would be an easy thing, no doubt, to select a few American prints below the average of English quality, and *vice versâ*, but it would be rash to generalise from this that American prints were inferior to English, or English to American.

Dr. Jeserich Anticipated.—During 1864, according to a Canadian contemporary, a forgery of ten thousand dollars, represented in two cheques, was discovered in the Assistant Treasury in New York, and came to be a question of the assistant treasurer, who accepted the cheques, or the auditor, whose name was signed to them, standing the loss. The assistant treasurer testified that the signatures of the auditor to the two cheques were genuine, and refused to admit a possibility of forgery, and claimed to be able, through his experience, to tell to an absolute certainty whether a signature he was at all familiar with was genuine or forged. The assistant treasurer at New York was, at that time, a very important personage, coming in importance directly after members of the Cabinet, and the friends of the auditor, who had perfect confidence in his integrity, awakened to the fact that they must find evidence of an unmistakable and fully convincing nature at once in order to clear their man. The means they adopted as a last resort, and which proved successful, was photography. Enlarged photographs of the two forged cheques in question were made, which showed, so conclusively and clearly that none could doubt, the false, traced letters of the names over which the letters in ink had been written. The tracings had then been cleverly erased so as not to be visible to the eye, but were brought out in startling clearness by the camera. The auditor was cleared of all responsibility, and the assistant treasurer, besides standing the loss, was so mortified at the evidence of his cleverness (?) in detecting forgery of a signature that he had seen thousands of times, that he immediately resigned his office.

DEVELOPMENT OF WEAKLY PRINTED POSITIVES ON GLASS AND OPAL.

[*Photographische Correspondenz.*]

Referring to the development of insufficiently printed proofs on celloidin, Obernetter, aristo, Mignon, and similarly prepared papers, as reported in our last number, further experiments have been made by the author with a view to developing glass positives and opals on plates coated with printing-out emulsion.

The experiments were made on "chlor-silber-gelatineplatten zum Auscopiren" by Schattera, of Vienna.

The plates were copied sufficient only to show a faint impression—a mere, but distinct, outline—and then developed by means of an acid hydroquinone, or pyro developer.

As these plates are not in any way liable to fog, and will stand a comparatively energetic treatment, the developer had consequently to be modified.

For red and violet tones the following hydroquinone developers are strongly recommended:—

	I.	II.	III.
Water	1000 parts ..	1000 parts ..	1000 parts.
Hydroquinone ..	15 „ ..	15 „ ..	15 „
Sulphite of soda..	50 „ ..	50 „ ..	50 „
Citric acid	3 „ ..	— ..	—
Acetic acid.....	— ..	5 „ ..	—
Tartaric acid	— ..	— ..	5 „

These developers result in clear, colourless solutions, which will keep in good condition for a long time. They are best used at a temperature of 68° to 77° Fahr. If the temperature is too low, development will take place but slowly. The plates are exposed in diffused daylight not longer than from five to fifteen minutes. During development the tray has to be kept rocking. The combined toning and fixing bath is that recommended in my last contribution, but diluted with equal parts of water.

For the production of yellowish-red tones, which are very effective with glass positives, the developed and washed picture is fixed in a neutral twelve per cent. solution of hypo, and is then transferred to the combined toning and fixing bath until it assumes a slightly reddish tone, when it is at once withdrawn and washed for some hours in running water.

Sepia brown tones are obtained with—

Water	1000 parts.
Hypo	100 „
Acetate of ammonium	100 „
One per cent. solution of chloride of gold ..	30 „

By another method red tones are produced by fixing the developed plate in a neutral fixing solution and transferring the same to the toning bath recommended by Eder and Pizzighelli,* to which for each 1000 parts of solution half a part of phosphate of soda has been added. The picture will quickly take a peculiar yellow red tone, which, on drying, changes to a beautiful, brilliant red.

Violet, purple-violet, and blue-black tones are obtained by longer or shorter immersion in the combined toning and fixing baths.

The hydroquinone developer No. I. can be used for several plates in succession, and such already used solutions act at once as developer and intensifier, owing to the considerable quantity of silver salts which they dissolve out of the coating of the plates. After standing for some time, the silver will be reduced to the metallic state, and the solution will turn muddy; warmed on the water or sand-bath, the sediment will, however, soon settle, and, after filtering, the developer may be used afresh.

Developers Nos. II. and III. work somewhat differently and develop quicker, giving at the same time purplish-violet tones, which in the neutral fixing bath are, however, lost. If these developed and well-washed plates are fixed in a weak solution of hypo and ammonia, or a mixture of ammonium and carbonate of ammonium (ten per cent. solution), they will, after washing and drying, show a splendid ruby colour, which cannot be obtained by developer No. I.

The fixed positives have in all cases to be well washed in running water, or they will, after some time, show yellow whites.

Developers with pyrogallic acid work still quicker, and by their means dark violet and black tones are easier to obtain. The developer best suiting these plates consists of

Pyrogallic acid	20 parts.
Water	1000 ,,
Citric acid	16 ,,
Sulphite of soda	50 ,,

It will develop vigorously and rich, giving the positives a brown colour, which afterwards, in the combined toning and fixing bath, changes to a violet bluish-black, and black tone. It is also best suited to plates showing, to commence with, a very faint impression only, as by its employment all harshness is avoided.

To the practical photographer this process offers many advantages; it makes him practically independent as regards duration of exposure. Under or over-exposure will no longer trouble him; from ten to fifteen minutes' exposure to diffused daylight will in all cases be sufficient to obtain an impression, which can be easily and reliably developed into a good picture.

A further and very definite advantage consists in the absolute absence of grain, which will make this method especially adapted to the production of enlarged glass positives, the colour of which can be had at will from a red to a violet and black tone.

It is equally well suited to the production of lantern slides by contact printing; and last, but not least, all operations may be carried out in gas, lamp, or subdued daylight. E. Valenta.

LANTERN SLIDES—HOW TO PRODUCE AND EXHIBIT THEM.

[Amateur Photographic Society of Madras.]

There can be no doubt that at the present day the use of the optical (*alias* "Magic") lantern is in universal request for purposes of instruction as well as amusement, and there also can be no doubt that an exhibition of lantern slides, even of moderate quality, affords a great deal of pleasure to the spectators, whether youthful or grown-up. An amateur photographer cannot, therefore, put his collection of negatives to better use than in preparing therefrom a set of lantern slides of the best quality his knowledge and experience will permit; he will find that his views, which, perhaps (especially if they be of small size), gain scant notice in the form of paper prints, will, when enlarged on a screen, receive the greatest possible attention from as many people as can be gathered together.

There are two very easy and cheap ways of making the slides—the old wet-plate process, and the recently introduced gelatine "lantern" plates.

To any one who ever worked the old wet process I should say stick to it, for with it you can get results as good as by any other process under the sun, and it is undoubtedly infinitely cheaper than any other mode; also it can be worked in the hottest weather.

Slides by the "collodio-bromide" process are also very beautiful, and

* A.	Water	1000 parts.
	Sulpho-cyanide of ammonium	40 ,,
	Hypo	3 ,,
B.	Water	1000 parts.
	Two per cent. solution of chloride of gold	60 ,,

quite equal to any others, but the ordinary amateur would find it very difficult to make a satisfactory emulsion, and about equally difficult to clean and coat the plates properly.

I should recommend the ordinary amateur, whose experience is solely in exposing ready-made plates, to keep to the "lantern" plates, which can be bought, of perfect quality, at one shilling per dozen. It will greatly conduce to the production of first-class results, if the developer be also bought ready made from the manufacturers of the plates.

I will first describe my apparatus, which is set apart entirely for the production of lantern slides and stereoscopic transparencies: A small camera made roughly of teak wood—it consists of a back and a front joined by a bellows made of a piece of brown paper glued between two pieces of black cloth (silesia); the baseboard is a plain piece of teak with a quarter-of-an-inch slot cut along the centre, through which a small screw passes to fix the back at the proper focus; the front is, of course, screwed to the baseboard, and has a rising and falling piece of wood on which the lens is fixed. The baseboard has a guide piece screwed on each side, between which the back slides, and is thereby kept parallel with the front. The lens should be a short focus rapid symmetrical.

A dealwood box, with four sides and a front, but no back: the front is provided with grooves in which the negative fits and has a series of smaller frames to hold negatives smaller than the largest size; in my case the largest size is $6\frac{1}{2} \times 4\frac{3}{4}$, and I have frames for 5×4, $4\frac{1}{4} \times 3\frac{1}{4}$, and $3\frac{1}{4} \times 3\frac{1}{4}$ negatives.

A sheet of plate glass, 15×12, ground on one side to diffuse the light when it is not possible to point the apparatus to the clear sky.

A piece of cardboard, which rests on top of camera and negative frame, and is, I find, quite sufficient to keep off outside light, and it has an additional recommendation in that it is very easy to get at the lens to remove or replace the cap or stop.

A flat board, about thirty inches long and six wide by one thick: it has a slot $\frac{3}{8}$ inch wide up the centre along which the screws travel, fastening the camera and negative frame at their proper distances apart. It stands upon four solid legs, the smaller pair being about six inches high, and the larger of sufficient height to raise the board to an angle of 30° to 45°.

A plain dealwood table, the top being such a height from the ground as will enable you to sit comfortably on a chair to do your focussing; the table should be big enough to accommodate, not only the apparatus, but also a box of negatives, focussing glass, and sundry other things.

The camera and the negative frame are fastened to the board by screws about $3\frac{1}{2}$ inches long with wing-nuts.

The camera takes quarter-plates, but to use it for plates $3\frac{1}{4}$ inches square, all that is necessary is to fasten a piece of wood at each end of the interior $\frac{1}{2}$ an inch wide—this leaves a space in the centre $3\frac{1}{4}$ inches square. The plates rest on four silver pins, which is a necessity in case of using wet plates, and for the same purpose the lower part should be thickly coated with Japan to prevent warping from the drips from the plates.

The whole apparatus (stand, table, camera, dark slide and negative holder) was all made by an ordinary carpenter from my rough sketches, the total cost of everything was under Rs. 20. The bellows I made myself.

Of course, any ordinary camera, quarter or half-plate, may be used in place of a special one, and the ordinary dark slides can very easily be adapted for the gelatine lantern plates; for wet plates it would be very advisable to have a single slide made specially, as ordinary double dark slides would not be improved by the use of wet plates therein.

The table, with the apparatus, can be placed in a verandah or close to a window in a room with the higher end of the board pointing to the sky.

Placing the negative in the holder with the gelatine side facing inwards to the lens, focus the picture by pushing the camera bodily up and down the board, clamp it and finish the fine focussing by the sliding back of the camera, and finally with the lens if it be provided with rack and pinion. The use of a magnifying focussing glass is very essential, as the finest possible adjustment should be made for lantern slides.

On the ground-glass side of the focussing screen you should rule lines of various sizes and shapes to suit the masks you propose to use; it used to be the custom to have every slide (no matter what the subject might be) of one shape and size to suit the dissolving view business, but it has of late years been realised that the aperture in the mask should be adapted to the picture, and not that the view should be frequently spoilt by cutting it to one particular shape.

When satisfied with the adjustment of focus and the shape and size of the picture on the screen, get the dark slide with the prepared plate wet or dry, remove the screen, insert the slide, and expose the plate in

the usual manner for the required time, shut up the slide, and take it to the dark room for development, &c.

I think it will be sufficient for one evening if I give details for two processes. 1st. The old wet-plate process. 2nd. The recently introduced gelatine "lantern" plates.

Wet-plate Process.—The apparatus required and the chemicals used in this process are as follows:—Glass bath, in a wooden case, with glass dipper; collodion pourer, to contain about four ounces; clean glass plates, 3½ × 3½—they should be thin and white. Iodised collodion, nitrate of silver, ferrous sulphate, potassium cyanide, glacial acetic acid, alcoholic tincture of iodine.

Collodion.—Mawson's or Thomas's ordinary collodion, iodised as long as possible before it is required for use; it should be a deep reddish-orange colour.

Silver Bath.

Nitrate of silver	250 grains.
Nitric acid	1 or 2 drops.
Distilled water	10 ounces.

Developer.

Ferrous sulphate (green crystals)	200 grains.
Glacial acetic acid	4 drachms.
Distilled water	10 ounces.

Fixing Bath.

Cyanide of potassium	240 grains.
Water	20 ounces.
Tincture of iodine	2 or 3 drops.

To clean the plate, rub it well on both sides with a little whiting in water, or with tripoli powder in methylated spirit with a little ammonia; then rinse it in hot water, and dry it with a clean cloth free from fluff. The plates should be as nearly chemically clean as possible to ensure freedom from streaks and stains; you may be sure of one thing—you cannot make them too clean!

Silver Bath.—Dissolve the silver in the water, put it in the sun for a day, add the acid, shake well up, and filter into the glass bath. The solution should be perfectly bright and clear; if not, it should be re-filtered.

Developer.—Mix the acid and water together, dissolve the iron in the mixture; filter if necessary, and keep well corked.

To coat a plate: Take a clean one in your left hand by as little of one corner as possible, pour on to the centre a pool of collodion, enough to cover half the plate (first dusting the plate with a broad camel-hair brush); let it run first to the right far corner, then to the left far corner, then as near as possible to your thumb without touching it, and pour off the surplus by the remaining corner. Do all this quietly and deliberately, without too much delay; then raise the plate vertically and rock it, so that no streaks may form in the film. Drain the plate well, but do not let it get dry anywhere; place it on the dipper, face outwards, and lower it into the bath with one continuous quick movement; move the dipper slightly to and fro for a few seconds, and then let it rest for a minute or two.

Raise the dipper gently for a moment, and at first you will observe that the bath solution runs down the face of the plate in streaks; but very soon you will see that it runs smoothly all over the surface, which has now changed to a creamy state from the formation of iodide of silver in the collodion film.

Drain the plate as closely as possible, blotting off the last drop or two, and cleaning the back with a piece of blotting-paper; place the plate face downwards in the dark slide, which should be kept vertical to prevent the bath solution running back in streaks over the face of the plate.

Expose the plate in the camera for the proper time, and return without delay to the dark room for development. It is most difficult to say what is the proper exposure, as it depends upon so many different things; but I may say that reducing a half-plate negative to 3 × 2½ inches, using a lens with aperture *f*-16, negative clean and not over-dense (such an one as will give a brilliant silver print in the shade), pointing to clear sky without the ground plate-glass, the exposure would be about forty seconds. The ground glass increases the exposure about forty per cent.—a thin negative would want, perhaps, fifteen to twenty seconds, while a dense one may require three or four minutes. Nothing but practice will teach exactitude, and the most experienced will sometimes be considerably out in his calculations.

To develop a wet plate, take a small quantity of the iron solution in a cup or measure—two drachms are ample for a lantern plate—and flood the plate with one even sweep. Care must be taken not to let the solution strike the face of the plate too hard, and not to let more of the solution than you can help run over the sides of the plate.

To any one accustomed only to gelatine plates it will appear very surprising to see the very short space of time required to develop a wet plate. The whole operation is over before a gelatine plate would show any signs. When sufficient density has been obtained, rinse the plate under a tap or from a jug of water, and drop it face upwards into the fixing solution.

The fixing bath, being a most deadly poison, had better be kept outside the dark room, the fumes being most unpleasant and headachy. This operation also takes a very few seconds, and after an amount of washing that would be wholly insufficient for a gelatine plate, the plate may be toned or put away to dry at once. The toning bath may be either—

Chloride gold	1 grain.
Water	10 ounces.

Or,

Platinum tetra-chloride	1 grain.
Nitric acid	1 drop.
Water	8 ounces.

The first gives purple tones, and the other one black tones; when toned sufficiently, wash for a while and dry. The platinum stock solution should be neutralised with soda carbonate before adding the water and nitric acid.

When quite dry, the high lights should be perfectly clear glass. With some collodions, however, there is a faint veil over the high lights, which may be removed by varnishing. A "crystal" varnish of dammar, dissolved in benzol, or the ordinary negative varnish, diluted with about one-third of alcohol, will be found suitable, and all varnishes should be carefully filtered before use. In my opinion, all collodion slides, and, indeed, all slides by any process, should be varnished.

Gelatine Lantern Plates.—These may be used either for contact-printing or for reducing or enlarging in the camera. Nearly all my experience has been with Thomas's plates, and I have never had cause to regret having kept to that one brand. I have used some sixty or eighty dozen, but have had to reject none on account of faults in the plate, although I have had to reject a good many for my own mistakes and carelessness.

It is possible with these plates and the developers recommended by the makers to obtain almost any tone from black to red. I prefer keeping to black tones, for there are several advantages to be gained thereby, not the least being that the time of exposure and time taken up in developing are at their shortest. The results are more certain, and in my experience the delicate tones of purple and brown observable by transmitted light are quite lost when shown on the screen with oil-light. Perhaps the oxyhydrogen or electric light may allow these delicate tones to be observed on the screen, but these are practically unobtainable in India.

The makers themselves give the time of exposure and development as ranging from two minutes twenty-five seconds for black tones to thirty-six minutes for red tones (for reduction in camera), so the gain in time is very real.

I shall here content myself by giving details for black tones alone; any one wishing to get warmer colours can get the fullest particulars from the descriptive memorandum issued with the plates.

Reduction in camera from half-plate as before, lens with *f*-22 stop, negative pointing to clear sky *with* sheet of ground-glass one and a half inch distant from negative, which if a clean one, not too dense, will take about forty-five to sixty seconds, the developer being—

1.

Sodium hydrate (caustic soda)	160 grains.
Distilled water	20 ounces.

2.

Hydroquinone	160 grains.
Sodium sulphite	2 ounces.
Citric acid	60 grains.
Potassium bromide	40 ,,
Water (distilled)	20 ounces.

For use, take a quarter of an ounce of each, and add half an ounce of distilled water, making one ounce in all.

Develop until slightly more dense than you wish the finished slide to be, as they lose a little in the fixing bath, which is made thus:—

Hyposulphite of soda	5 ounces.
Sodium sulphite	1 ounce.
Sulphuric acid	1 drachm.
Water	to 20 ounces.

Dissolve the hypo in fifteen ounces of the water and the sulphite of soda in the remaining five ounces; add the sulphuric acid to the latter, and then pour the acid sulphite solution into the hypo, and well mix; keep well

corked, and it will last for a very long time, but personally I always used a new fixing bath for each batch of slides.

If you find the slide, after fixation, to be rather too dense, you can reduce it very easily by applying a weak solution of hypo with a few drops of solution of ferridcyanide of potassium (Farmer's reducer).

After fixing, wash well (face downwards, if possible) for an hour or two, and dry in a place free from dust.

Contact-printing by artificial light may be done in the evening. The exposure for a clean negative as before, two feet from a Silber burner No. 1, wick clean, cut quite level and turned up just short of smoking globe perfectly clean, kerosine oil 150° water-white, would be about thirty seconds. The developing, &c., is exactly as for camera reductions.

These bromide transparencies can be toned by the uranium nitrate and ferridcyanide of potassium toning solution recommended by the Eastman Company for their bromide paper. The solution is made up of—

Uranium nitrate	9 grains.
Potassium ferridcyanide	8 „
Glacial acetic acid	5 drachms.
Water	16 ounces.

Tones, from black, through browns to red, are very easily obtained with this solution, and when the desired tone is obtained the transparency should be washed *only until* the slight yellow stain in the high lights has been removed; any longer washing only results in the removal of the colour previously obtained.

When your slide is finished and finally dried, see if any spotting or retouching be required, and, if so, attend to it carefully; then varnish it as before described for wet-plate slides. Gelatine plates are much more likely to get spots and blemishes from dust and other causes than the old wet plates, and extra caution is, therefore, very advisable. With wet plates, when the washing is finished, a dip in hot water will dry the slide in a very few minutes; but such a procedure is not possible with gelatine plates.

To mount the slide, get a thin glass 3¼ inches square, as white as possible and quite clean, fit a suitable mask between the two glasses, and bind the whole together at the edges with strips of gummed paper. To distinguish your slides from those of any one else, you should bind the tops and bottoms with strips of paper of a different colour to what you use for the sides. I generally use *orange* paper for tops and bottoms, and *black* paper for the sides. Of course, this can only be done by cutting all the strips into pieces 3¼ inches long; but I do this in every case, even when using the same coloured paper for all four sides.

The title of the picture can be written on the mask, in white ink if the mask be black, or in black ink if the mask be white; a label outside is equally useful, but is liable to get dirty. The slide may be considered to be ready to show when you have gummed two white circular spots of paper on the two top corners, and have cleaned the outsides of the two glasses. On one of the circular spots you can put its consecutive number, and on the other your own initials, date, &c. When inserting the slide in the optical lantern frame, these two spots should be at the bottom next to the condenser.

With an oil lantern, the main points are to see that the outside of the lamp is quite clean and dry, that the glasses of the condenser and front lens are in their proper places and quite clean, that the best oil procurable be used, and that the wicks are clean and cut quite level. After all the wicks are lighted, they should be turned down quite low and raised little by little every few minutes until at their full height just short of smoking; ten minutes over this operation are not too much to spend. Hughes' "Pamphengos" is the best oil lantern I have ever seen anywhere, and can be obtained in several qualities from two to six guineas.

FRED. DUNSTERVILLE.

CLAIM £10, BALANCE FOR PHOTOGRAPHIC STUDIO AND CONTENTS.

WHITTAKER *versus* MCDONALD.

MR. C. N. WILSON, barrister, appeared for the plaintiff, and Mr. White for the defendant.

Mr. Wilson stated his case as follows:—In this case the plaintiff sues for a balance of 10*l.* for a studio and its contents, situated at Kirkby Stephen, and sold by the plaintiff to the defendant on September 12 last year. It appears Mr. Whittaker is a photographer, and carries on business in this town. He had also a branch studio at Appleby and one at Kirkby Stephen. The defendant, McDonald, who for a good many years had been an assistant to Mr. Whittaker in Penrith, had also helped him with the business at Appleby and Kirkby Stephen. Mr. Whittaker, not wanting him in opposition at Penrith, undertook to sell the studios at Appleby and at Kirkby Stephen for the purpose of enabling him to carry on the business of a photographer at those places, but distinctly on the understanding that he was not to carry on a business in opposition at Penrith, and the prices arranged were 20*l.* for each of the studios. Ten pounds was paid down on account, and the balance was demanded. There was a balance of 30*l.* left over. Matters all went on very well for a short time, but then the defendant, McDonald, in direct opposition to what he had agreed to, went and sold the studio at Kirkby Stephen, and it is for the balance due on that studio that we are now suing. I call the plaintiff, Mr. Whittaker.

Mr. Charles J. Whittaker (examined by Mr. Wilson). Are you a photographer carrying on business in this town?

Mr. Whittaker. Yes, I am.

Q. Now, you have been in business since 1887?

A. In February, yes.

Q. Previously you were in business at Appleby?

A. Yes, in May 1885.

Q. Before that you were in partnership with Mr. Abel McDonald, Mr. Edward McDonald's brother?

A. Yes.

Q. And you dissolved partnership in 1888?

A. Yes.

Q. Now, had you the branch business at Appleby?

A. Yes, in Leslie's Yard, Appleby.

Q. I think the defendant, McDonald, came as an assistant to you?

A. In December 1887.

Q. How long did he act for you?

A. Six months.

Q. And you sold him the Appleby business?

A. Yes, for 13*l.*

Q. I think he carried on the business for some time?

A. Yes.

Q. And you purchased the business back again?

A. Yes, I did so.

Q. Did not he come to you again in 1888 as an assistant?

A. Yes.

Q. And he worked regularly for you until when?

A. Until September 1891.

Q. What were his wages?

A. When he first came to me he had 15*s.* a week, then 20*s.*, then 25*s.*, then 30*s.*, and the last twelve months 35*s.*

Q. I think he gave you notice in September last year?

A. Yes.

Q. Had you any conversation with the defendant, Mr. McDonald, about the purchase of these places at Appleby and Kirkby Stephen?

A. He proposed that I should sell him the places.

Q. And you did not consent?

A. I did not consent at first.

Q. But finally you did?

A. Yes.

Q. What did you sell him these studios for?

A. The actual terms were 40*l.*

Q. 40*l.* each?

A. 20*l.* each.

Q. What were the terms about carrying on the business?

A. I pointed out to him that I would not like him to start in opposition to me in Penrith, and, if he would only be content with carrying on the business at Appleby and Kirkby Stephen by himself, I would let him have them on certain conditions.

Q. What did he pay you down?

A. He paid me 10*l.* at Martinmas, but not in full.

Q. Was there a balance of 30*l.* owing to you?

A. Yes.

Q. Now, I think he is still carrying on the business at Appleby, and is still in possession of that studio?

A. I believe so.

Q. What about the Kirkby Stephen studio?

A. He has sold it.

Q. Whose name is over the door?

A. Mr. Yeoman. I saw it at Kirkby Stephen, and it was Mr. Yeoman.

Q. What was the arrangement?

A. He was to carry on the business on his own account.

Cross-examined by Mr. White.

Q. Was the agreement with Mr. McDonald in writing?

A. Yes.

Q. Where is the writing?

A. McDonald has it.

Q. You have had a copy of this agreement?

A. No, I have not.

His Honour. I cannot allow any more evidence to be given about it.

Q. Do you produce the document?

Mr. White. He has had a *subpœna* to produce the document.

His Honour. If you have anything else to ask, apart from the agreement, you had better do so.

The agreement was then put in by Mr. White.

His Honour. I do not know what the studio or its contents may consist of.

Mr. Wilson. I object to that agreement; it should have a 5*s.* stamp.

His Honour. If it is not properly carried out, the plaintiff is entitled to have the contents of the studio back again.

Mr. Wilson. We rely upon part payment of this 40*l.*

His Honour. If it is a written document, you must rely upon it. I cannot receive evidence without it. If there is no stamp, I cannot receive it. That writing is not before me, and therefore I cannot receive any evidence upon it. That is your copy?

Mr. White. That is my copy.

His Honour. I will tell you my view of the subject. There is not the slightest doubt about it that, if there is any agreement, it must be produced. Therefore all the evidence that has been received I must strike out. All this evidence that he sold these things at Kirkby Stephen and Appleby for 20*l.* a piece must be struck out. As the case stands at present, I have no evidence at all. I must have the original of this document.

Mr. Wilson. Have you got the original?

Witness. I have a duplicate.

Mr. Wilson. Will you produce it? [Witness produced the document.]

Mr. Shepherd. This gentleman (Mr. White) is my clerk and with your Honour's permission I will address you. The agreement is in writing, and before it is produced I think there is no case.

His Honour. The burden of proof is on the plaintiff.

Mr. Wilson. We rely upon the fact that there have been goods sold above the value of 10*l.* and there has been part payment. We rely entirely upon the evidence.

His Honour. It was an agreement in writing.

Witness here handed in duplicate of document.

Mr. Wilson. We do not put this in, your Honour.

His Honour. If you do not put this in, there is an end to the case.

Mr. Shepherd. Then I apply for the verdict with costs.

His Honour. If you do not put that in, my verdict is for the defendant in the usual way.

Verdict for the defendant accordingly.

Our Editorial Table.

Workshop Receipts (Fifth Series).

E. & F. N. Spon, 125, Strand, W.C.

In this, the most recent of Messrs. Spon's useful series of *Workshop Receipts*, the subjects embrace, *inter alia*, laboratory apparatus, cements, copying, distilling, filtering, lacquers, magic lanterns, waterproofing, boatbuilding, and barometers. So far as we can perceive, the articles are entirely made up of selections judiciously made from writings on the various topics treated; this, however, forms no objection to their utility, while the source is freely acknowledged.

Watson & Sons' New Catalogue.

A most compendious and useful catalogue, which contains everything necessary for the photographer, whether amateur or professional. In this the "Acme" camera of the firm finds premier position, which is well justified by its merits. We observe that, since our former notice of this camera, aluminium has been utilised in its metallic fittings, by which a considerable reduction in its weight is secured. Other cameras, for studio and field, are described, and of hand cameras there are not a few. Lenses made by this and other firms are fully tabulated, together with stands, dark and projecting lanterns, backgrounds, enlarging appliances, and chemicals. The catalogue, of ninety pages, is a highly suggestive one, and will be perused with advantage.

A Guide to Electric Lighting.

By S. Bottone. London: Whittaker & Co.

Mr. Bottone has for many years been recognised as a lucid writer on all topics connected with electricity, and in this work of 194 pages he treats the subject of electric lighting in a popular manner, capable of being readily comprehended by the general public. He gives accounts of the various batteries employed in the generating of electricity for lighting, coupled with discriminating observations on the special capabilities of each, together with drawings and descriptions of the lamps in general use, whether incandescent or arc. The work is most copiously illustrated.

The *Idler* for May, we are happy to say, shows a distinct advance both in the quality of its letterpress and illustrations upon previous numbers. We are pleased to learn that our old contributor, Mr. Conan Doyle, is to supply fiction to an early issue.

"Illustrations" for April, edited by Mr. Francis George Heath, contains numerous illustrated stories and articles of a sufficiently diversified character to be interesting to the general reader. There are also portraits and biographies of such notable individuals as Sir Charles Dilke and Mr. Holman Hunt.

PATENTS COMPLETED.

Improvements in Photographic Cameras.

No. 5213. George Percival Spooner, Bron-y-garth, Portmadoc, North Wales.—*March* 24, 1892.

The object of my invention is to effect improvements in the construction of photographic cameras.

I construct my improved apparatus in two compartments, preferably one above the other. The upper compartment contains the lens, bellows, focussing screen of ground glass, swing-back, shutter, and other fittings; and the lower compartment contains the plates, previous to, and after, exposure.

The plates are held in sheaths, and the sheaths are placed in a drawer fitted with grooves on each side (hereinafter called the "plate drawer"). The sides of the plate drawer, between the grooves, are slotted to permit the plate lifter to pass up and down.

The plate drawer is placed in a case (hereinafter called the "plate box"), so as to be capable of sliding in and out of the same, as in the case of an ordinary drawer.

The plate drawer is closed and locked so as to exclude the light, or it may be opened in a dark room, or within the camera, by suitable methods.

The plates are raised from the plate drawer by lifting bars, consisting of a pair of curved levers, with suitable appliances attached thereto. The lifting bars have toothed racks, and engage toothed quadrants on each side of the camera. The quadrants are fast on an axle, and are actuated by a suitable crank or lever outside the case, which crank or lever is fixed to a cam wheel hereinafter described. The sheath is lifted by turning the crank until the sheath is in the position previously occupied by the focussing screen in the camera compartment.

Previously to the passage of the sheath from the plate drawer to the upper compartment, the lense shutter and dark door are closed; a slide between the plate-box case and the upper compartment is opened, and the focussing screen is moved back to admit of the sheath taking its place. The sheath then passes into the upper compartment, and the slide is closed, the slide sustaining the sheath. The plate is then in position for exposure, and, after exposure, it can be returned to the plate drawer by a reversed movement of the crank.

When the sheath has been returned to the plate drawer, the focussing screen takes the place of the sheath, and the plate drawer is moved on ready for the next operation.

The several shutters and other doors are actuated by a cam wheel, with separate cam grooves for the several motions.

The focussing screen is held in position preferably by four bell-crank levers, two on each side.

An opening is formed in the back of the upper compartment, so as to enable the picture to be properly focussed on the screen. This opening is closed by a shutter or door during exposure.

The camera is also fitted with screws, nuts, clips, and other means for adjusting, fixing, and arranging the several parts of the apparatus.

The cam or cams may be driven by a connecting rod attached to a coiled spring, previously wound up, a rack being formed on the connecting rod, driving a pinion on the cam. An escapement lever, with suitable attachments, is used to cause half a revolution or thereabouts of the coil spring to lift the plate, and the other half revolution to lower it.

Improvements in and in Connexion with Photographic Cameras.

No. 9042. Edmund Hawthorn Micklewood, 5, St. Michael's-terrace, Plymouth, Devonshire.—*March* 26, 1892.

This invention relates to a means of exposing sensitive plates or films in a camera so as to give a due ratio or balance of exposure to all parts of the

picture. In a landscape, for instance, the sky, distance, and foreground each receive a varying time of exposure by which the best effect is produced.

To obtain this result, I construct in front of the camera a dark chamber, and in the front of the dark chamber provide a rectangular opening proportional to the size of plate the camera is adapted to take. In this opening is a rising and falling shutter, actuated and controlled by suitable mechanism.

It is desirable that the distance of the shutter from the lens should be proportional to the focal length of same.

I should explain that what I mean by a rising and falling shutter is any shutter which is lifted upwards until the aperture is completely open, and, after the proper time for exposure has elapsed, is then lowered; and my reason for this arrangement is that by this means, when used at a distance from the lens in a dark chamber, I am able to allow the sky in a landscape scene, for example, less exposure than other parts of the picture. It may be ascertained by experiment that, if a shutter works immediately over or in front of a lens in the ordinary manner, that the picture on the sensitised plate is not obscured in proportion to the movement of the shutter, and that with shutters, as usually applied to the lens, supposing the moving part to have passed through a small portion only of its travel, even then the whole picture is visible on the focussing screen, whereas I have found that, by interposing the dark chamber between the lens and shutter, the commencement of the raising of the shutter causes the sensitised plate to be exposed only partially, and to become more and more exposed in accordance with the opening of the shutter, the sensitised plate becoming in like manner gradually obscured as the shutter closes, whereby I am able to give the sky, distance, and foreground each a varying time of exposure. It will now be understood that by the term "rising and falling shutter" I do not limit myself to any particular form or construction of same, but I may employ any form or construction of shutter which will produce or act with the herein-stated effect.

It is a well-known principle in optics that the rays passing through the centre of a lens form by far the most perfect image when focussed and thrown on any surface to receive them, hence the use of diaphragms to cut off the outside "pencils" and use only or principally those passing centrally.

From this as a starting-point, and as the result of observation and experiment, I have discovered that shutters acting in close juxtaposition to the lens act as inferior-shaped diaphragms, causing the worst part of the lens—viz., the edges—to do the work during a large proportion of their action, as when a lens is only partially uncovered from the edge the image is being formed and transmitted by the marginal portion only.

Diaphragm shutters working centrally are free from this defect, but as they expose the plate evenly they fail to give a due balance of exposure as required for the best results to the several parts of the landscape.

Again, the image transmitted by a lens is at all times a circular one, of which in photographic cameras a rectangular portion taken centrally only is used, and with cameras as usually constructed the remainder is thrown on the top, sides, and bottom of the camera, so introducing light into the camera not used in the formation of the image, and which, with the exceedingly sensitive plates now used, degrades the image.

In the new combination of dark chamber and shutter in front of the lens now introduced all these defects are obviated, as the former frames the view in front of the lens, and so only allows light actually falling on the sensitive plate to pass into the camera, and the shutter, being applied to the front of this chamber, at a distance from the lens, in no way interferes with the full and efficient action of the latter.

A suitable proportion for the rectangular opening provided in front of the dark chamber, and in which the shutter works, I have found to be half the linear dimensions of the plate the camera is adapted for; the rectangular opening is adjusted to, or situated at, such a distance in front of the lens that only the view actually falling on the plate is transmitted, and all side-light is cut off; thus, with long-focus lenses, it will be evident that the shutter aperture should be placed further away, and with shorter-focus lenses, brought closer.

The shutter being placed at a distance from the lens, the latter photographs the movements of the shutter; hence, as the said shutter moves up and down, the sensitive plate is exposed as if by a rolling curtain which starts from the foreground and returns to the same, the result being that the most delicate cloud effects existing are secured, together with a fully exposed landscape, in a manner far superior to that hitherto obtained.

Having now particularly described and ascertained the nature of my said invention, and in what manner the same is to be performed, I declare that I am aware that it has been heretofore proposed to employ a shade outside the lens of a camera to cut off extraneous light, and I am also aware that a dark chamber has been proposed to be employed in front of a photographic lens. Photographic shutters which have a lifting or rising and falling motion are not in themselves new, I therefore lay no claim to these parts taken alone or separately, but what I do claim is:—1. In photographic cameras, the combination with a lens and a rising and falling shutter of a dark chamber, arranged between the lens and the shutter, whereby sensitive plates or films are exposed so as to give a due ratio or balance of exposure to all parts of the plate or film, and to exclude all extraneous light, all substantially as herein set forth. 2. The general arrangement and construction of photographic cameras substantially as shown on the accompanying drawings, the prominent feature being the combination of a dark chamber arranged between the lens and a rising and falling shutter as set forth.

AN APPLIANCE FOR ATTACHING TUBES OR CYLINDERS TO FLAT SURFACES, PRIMARILY APPLICABLE FOR ATTACHING PHOTOGRAPHIC LENS TUBES TO CAMERAS.

No. 8934. HENRY GRANT MADAN CONYBEARE, The Hut, Ingatestone, Essex. —*March* 26, 1892.

AN appliance in accordance with my invention is represented by the drawings annexed.

I employ a flange, to be attached to the camera front by screws. Into this flange I screw a ring having a milled edge. On the inside of this ring are fixed two or more studs. To the photographic lens or other tube is attached a flat ring or flange, having two or more notches cut in the edge, and corresponding with the studs fixed to the ring. On the surface of the flat ring, near one or all of the notches, I fix a small stud or studs.

In lieu of the above I make recesses in the screwed ring, and projecting pieces to the flat ring or flange attached to the lens tube.

PHOTOGRAPHIC SOCIETY OF GREAT BRITAIN.

APRIL 26.—Technical Meeting.—Mr. W. England in the chair.

Mr. ALEXANDER MACKIE said he was continually making collodion emulsion, and occasionally got variations which he could not account for. He showed samples of emulsion which, on drying, changed in colour to bright blue and green respectively. The first of these, when wet, was of a good colour. He suggested that possibly the formation of the bromide had something to do with the changes, and asked for explanations. He had not tried the emulsion in its various coloured states. He had noticed that if the bromide of ammonium had gone wrong it gave a grey film. In answer to questions he said the samples he showed were not of one batch. He always used collodion for lantern slides and transparencies. The minimum exposure was about one minute.

Mr. A. COWAN remarked that all commercial slides were made on wet plates.

Mr. MACKIE said that slides were never made by contact commercially, because of the wear of the negative; and went on to narrate a curious experience of Mr. E. W. Parfitt, who, when making some transparencies on gelatine plates, got admirable colours with clear lights at home, but entirely failed to get warm colours in Mr. Mackie's dark room. He suggested that commercial ammonium carbonate practically contains little carbonate, and might be carbamate.

Mr. T. BOLAS said that could only be determined by experiment. The difference in the respective formulæ was in the carbamate amidogen had replaced some of the hydrogen of the carbonate.

Mr. MACKIE said both samples were apparently alike.

In the course of further discussion on collodion emulsion, Mr. J. D. ENGLAND said he had recently had occasion to test a collodion emulsion made eighteen years ago by Mr. Warnerke. It gave very good results. It had become somewhat thin, but it developed up a clear and dense image.

Mr. H. Chapman Jones, the Hon. Secretary, exhibited some stereoscopic collodion transparencies made on different emulsions, the new mineralised methylated spirit having been used in the preparation of one of the emulsions, the other with the ordinary spirit. That prepared with the mineralised spirit was more sensitive than the other, and appeared to have no disadvantages to set against the extra sensitiveness. Practically speaking, it was advantageous. He had bought the mineralised spirit from the oil shop.

Mr. MACKIE pointed out that the transparencies made with the mineralised spirit were fogged, and did not consider the experiment conclusive.

The sensitometer readings gave eighteen for the collodion made with the unmineralised spirit, and twenty-two for the mineralised emulsion. Opinions, however, were divided as to the correctness of these readings, as also to the accuracy of Mr. Warnerke's claims.

During the evening Mr. H. A. LAWRANCE drew attention to an article in the *Correspondenz* dealing with the different-coloured images obtained with carbonate of soda and caustic potash in the developer respectively, and subsequently quoted an experiment of Herr E. Vogel, in which he emulsified silver bromide in gelatine, removed the gelatine by the eparator, and then emulsified

the haloid in collodion. By an exposure of five seconds the F line of the spectrum was obtained.

After further discussion the meeting closed.

LONDON AND PROVINCIAL PHOTOGRAPHIC ASSOCIATION.

APRIL 21,—Mr. J. J. Briginshaw in the chair.

Mr. H. SNOWDEN WARD, being invited to offer any remarks of photographic interest in connexion with his American visit, said that the principal thing which struck him was the bad printing exhibited by the professionals in general. American photographers rather prided themselves on their posing and lighting, but, speaking from a careful examination of New York and Philadelphia work, printing was their weak point. Their vignetting was not good, and in general the prints were faulty. He did not know whether this was to be accounted for by the inability of the workmen or cheapness. Almost all the paper used was freshly sensitised, and they were always told that it produced infinitely better results than the preserved paper; but the printing would not compare with London or provincial work. One thing he noticed, and that was, that large sizes were being much worked in the States, quarter-plate cameras being little known. The favourite small size was 5×4, but even that was little used. 7×5 was the fashionable size: it was used for stereoscopic as well as single-lens work. In landscape photography 48×20 was being used in films for panorama work. Mr. Jackson, of Denver, made it a speciality. One of the results of the use of such large sizes was that the sale of paper was necessarily great. Of the 52,000 reams of albumenised paper made by the Dresden Company, the United States took more than half, the remainder sufficing for the rest of the world. As to photographic societies, the Philadelphia Society and the Society of Amateur Photographers of New York had large premises, and, in fact, went in for everything on a large scale. Many of the Societies had more accommodation than any of the Societies in this country with the exception of the Camera Club.

The paper on *Photography as Applied to the Detection of Crime*, by Dr. Jeserich of Berlin, was read by Mr. A. Mackie.

At its conclusion, Mr. W. E. DEBENHAM mentioned that he had made some experiments on Dr. Jeserich's lines, but by a method reversed to that of orthochromaticism, using a screen dyed with *Bleu de Lyons*. He found it better to use coloured illumination.

A set of Indian and Colonial slides, lent by the Photographic Society of Great Britain to the Association as an affiliated body, was exhibited. These comprised eighteen views of Tasmanian scenery by Mr. F. J. Patterson, of Hobart, Tasmania; fifteen of similar subjects by Mr. Hanson; ten views of Cape scenery were contributed by Mr. C. Ray Woods; Indian scenery being represented by the work of Messrs. Valani & Pipistrello. The collection was much admired.

Mr. F. A. Bridge showed samples of linen and paper treated with an apparently non-actinic medium prepared by Messrs. Christy, of Fenchurch-street. Although intended for surgical purposes, it was the general opinion of the meeting that, if the colour was really non-actinic, the substances would answer well for dark-room illumination. Mr. Bridge mentioned that he had been informed that some of the paper had been exposed to two days' sunlight without bleaching.

Mr. Snowden Ward exhibited a negative which had been stripped from glass by means of a special celluloid solution prepared by Mr. John Carbutt, of Philadelphia.

Camera Club.—April 21, Mr. A. Deed in the chair.—Mr. PRINGLE exhibited a series of lantern slides, illustrating travels in Spain, including a set of pictures taken at a Spanish bull-fight, and some fine interiors and architectural subjects at Seville, Burgos, and elsewhere. Mr. Pringle gave an interesting description of the slides as the exhibition proceeded. Later on, other slides were shown by Messrs. Avent, Ferrero, and Leventhorpe. May 2.—Last social evening and smoking concert of the season will be held at the Club, and on Thursday, May 5 slides, of scenes on the Norfolk Broads will be shown by several members, the description being given by Mr. E. J. Humphrey. Other slides will follow.

North London Photographic Society.—May 3, Lantern Night, to which ladies are invited on the introduction of members.—In order to give opportunity of exhibiting to as large a number of members as possible, it is requested that those who have slides to exhibit will kindly make a selection of twelve from those which they may consider to be their best slides, and will send or bring them as soon as possible after 7.30 on the evening of May 3 with a list of the subjects, so as to allow of arrangement before commencing. The Indian and Colonial set from the Photographic Society of Great Britain will be shown.

Gloucestershire Photographic Society.—April 25, Annual Meeting.—The following were elected officers for the year:—*President:* Rev. Mowbray Trotter.—*Vice-President:* Mr. F. H. Burr.—*Committee:* Messrs. W. C. Beetham, H. S. Crump, W. J. Jenkins, A. H. Pitcher, T. G. Smith.—*Hon. Treasurer:* Dr. Hodges.—*Hon. Secretary:* Mr. W. Walwin. The Secretary's report showed the Society to be in a satisfactory condition financially and otherwise, and, with a series of outdoor meetings arranged, a successful season is anticipated.

Dunedin Photographic Society.—March 18, Second Annual Meeting.—The balance-sheet and annual report were read and adopted. The Society begins its third year with a satisfactory credit balance and an increased membership roll. During the year much useful work has been accomplished. Demonstrations by the members and lantern-slide exhibitions have been given at the monthly meetings. The yearly exhibition was this year held in conjunction with the Nelson Camera Club in Dunedin, and was pronounced a great success. The following officers have been appointed for the forthcoming year:—*Committee:* Messrs. F. M'cuson, C. Morris, W. Melville, R. A. Ewing, F. B. Smith, W. Williams. *Secretary and Treasurer:* H. Livingstone, Royal-terrace.

North Middlesex Photographic Society.—April 25, Mr. W. B. Goodwin in the chair.—Negatives made upon Imperial plates (samples of which had been distributed among the members at a previous meeting) were passed round for inspection, the consensus of opinion of those who had tried them being that they were good in quality and at least as rapid as most ordinary plates. Mr. Gill then developed some plates which had been exposed by some of the younger students, explaining his methods as he proceeded. A number of questions on technical points were asked and answered, and Messrs. Warne and Gill passed round hand cameras of novel construction, and explained the methods of working them. Some curious and beautiful prints were shown, and a method of mounting prints to secure them from the effects of damp was explained by Mr. Cox. The first field-day of the season having been held on Easter Monday at West Drayton, when nine members attended, prints from the negatives taken on that occasion were entered for competition. The vote of merit was secured by Mr. H. Smith for his print entitled *Steady*, in which an angler, who had been fly-fishing, was anxiously directing his assistant to secure the catch. Mr. Smith then reported that eighteen members and friends had attended the field-day on Saturday, the 23rd inst., to Edgware and Stanmore. The next meeting of the Society will be held on Monday, May 9, when the last exhibition of members' slides during the season will be given.

Kensington and Bayswater Photographic Society.—April 25, Mr. J. E. Hodd in the chair.—Mr. J. HOWSON gave a paper on the Ilford gelatine printing-out paper and isochromatic plates. His demonstration was accompanied by specimens showing the difference of results obtained by variety in manipulation. He stated that gelatine printing-out paper was invented in 1885, and prints exist which were prepared in that year, and show no sign of fading or discolouration. The advantages claimed for this paper are its permanence, good printing qualities, its price, its convenience in cutting, and the absence of water-mark edges. Mr. Howson stated that the toning bath should never be warmed, as the effect of a bath much above 50° Fahr. would be to cause a yellowness of the print. The effect of insufficient washing previous to toning is to spoil the toning bath and affect the permanency of the prints. If burnishing is intended, the alum bath should be used. Mr. Howson next pointed out very clearly the difference between "isochromatic" and "ordinary" plates, and the advantages possessed by the former over the latter, as in the case of photographing flowers and trees. The plates are assisted in their isochromatism by the use of a yellow screen (of specially prepared glass) placed inside the camera, immediately behind the lens. The emulsion of these plates differs from that of the ordinary in that it contains "eoside of silver," a chemical which is extremely sensitive to yellow rays.

West London Photographic Society.—April 22, the President in the chair.—Mr. ROLAND WHITING read a paper on the *Artistic Improvement of Negatives*. A discussion ensued, which, together with the paper, embraced too wide an area to do justice to in a necessarily condensed report. The Secretary reminds the members to let him know by the 30th inst. whether they want more than one ticket for the dinner on May 13.

South London Photographic Society.—April 20, Demonstration of *The New Cold Bath Platinum Process*, by Mr. F. W. Edwards, the President.—The paper was first brought before the Camera Club Conference a week or two ago, and had not since been demonstrated at any Society, and was not yet purchasable by photographers. It differed from the old cold-bath process inasmuch as the platinum is used in the preparation of the paper, and not added to the developing bath. The troubles arising from evaporation of the developer, and the destruction of the dishes in the hot bath process, were done away with by the use of the new paper, as also were the difficulties caused by bubbles and streaks, Mr. Edwards stating that he considered it to be "the printing process of the future." Results could be got from their negatives which it would be simply impossible to do with the older method. The deposit of platinum is very much finer, and there is also a freedom from granulation. Velvety shadows are obtained with very pure whites. A portion of the print can be developed at a time without showing any line or marking, thus doing away with the necessity of using large dishes. By using the bath colder over-printed pictures can be brought up, and under-printed ones by using it warmer. It is impossible to over-develop a properly printed picture. Prints are made until a faintly printed image is obtained on the paper, when they are developed in a bath of oxalate of potash (one pound in sixty ounces of water). After development they are treated with three baths of hydrochloric acid, one in sixty, to remove the yellowness, and afterwards washed to get rid of all traces of the acid. The President, after demonstrating the working of the process, offered the prints for sale for the benefit of the funds of the Society, when upwards of 3*l.* was realised. The excursions to Canterbury (on Easter Monday) and Dulwich Village (April 23) were very successful, and many good negatives obtained.

Brechin Photographic Association.—April 20, Mr. H. Braid (Vice-President) in the chair.—The Secretary (Mr. J. D. Ross) was appointed delegate to the Photographic Convention meeting in Edinburgh during week beginning July 11. A letter was read from Mr. W. T. Stead anent the National Society of Lanternists, and a number of those present agreed to become members. Mr. J. Mackie, jun., and Messrs. Day & Maw (Forfar and Brechin Railway) were balloted for and admitted members. Set No. 2 of the American Lantern Slide Exchange were then exhibited, and evoked, on the whole, very favourable criticisms. The SECRETARY reminded the members of the desirability of having the set of slides illustrative of linen manufacture ready early in the autumn. Lord Provost VALLENTINE thought that, in view of the establishment of technical schools throughout the country, slides illustrating such subjects would be very useful. Mr. J. H. LAMB concurred, and it was agreed that, as soon as the slides were ready, and before a lecture was written to accompany them, they should be exhibited at a meeting, to which all interested should be invited. Mr. A. R. MCLEAN MURRAY, who read the notes on the American slides to Mr. Innes, who worked the lantern, and to the Chairman, closed a very pleasant meeting.

Derby Photographic Society.—April 19, Mr. R. Keene presided.—Mr. A. C. RILEY gave a lecture entitled, *The Production of Copper Plates by Photography*. This gentleman, in a very simple manner, described the process

dating from the time of Fox Talbot to the present day, showing, as he proceeded, copper plates in various stages of being produced. Mr. W. Morris, St. James's-street, was elected a member. Mr. Keene showed several prints by the new kallitype process, and a number of platinotypes were also shown by Mr. T. Scotton, which had been developed by a new method with excellent results. A library was started a short time ago, with which the members are well pleased, several of them making use of it.

Lincoln Camera Club.—The inaugural meeting of this newly formed Society was held in the large hall of the Church House on the 8th inst., and proved a great success, the attedance being large. The Mayor (Mr. W. W. Richardson) presided, and was supported by the Sheriff of the City (Mr. Alex. Trotter). In the unavoidable absence, through serious illness, of the President of the Club (the Rev. Dr. Stott), the inaugural address was given by the Rev. T. Gough, B.Sc., F.C.S., Headmaster of the Retford Grammar School. After indicating the aims of the Lincoln Camera Club as being the improvement of the quality of the work done by the amateur photographers of Lincoln and neighbonrhood, as the result of mutual co-operation and study among the members of the Club, assisted, as they doubtless would be, by the professional talent for which the city of Lincoln is so famous, the lecturer proceeded to give a rapid sketch of the aims and processes of photography, illustrating his points by means of a beautiful series of lantern slides, the work mainly of the President and himself. The contention that a photograph might be an artistic expression of the beautiful, and that the worker with the camera could recognise and perpetuate the beautiful alike in simple, homely, every-day scenes, and in the more striking phenomena of nature, was established by pictures of scenes on canal and river banks, the simple cottage, snow-clad churchyard, woodland groves, and the grandenr of our Cornish coast, with instantaneous pictures of terrific seas hurled up against its mighty cliffs by the fury of an Atlantic gale. Passing next to the processes of photography, by means of beautiful diagrams the lecturer explained the action of the photographic lens in the camera in the formation of the picture that falls upon the sensitive plate, showing the analogy in its action to that of the lens in the human eye. The changes produced in the sensitive film by the action of the light, and the nature of the negative picture thus obtained were next discussed, and some of the processes for obtaining positives explained. Finally, the lecturer showed the extraordinary extent to which photography was now, by aid of the lantern, applied to the teaching of many branches of knowledge, illustrating this part of the subject by a large number of beautiful slides on astronomy, botany, zoology, and microscopic objects, showing what a powerful instrument photography and the lantern have placed at the disposal of teachers of these subjects. Information respecting the Society can be obtained of Mr. W. R. Lilly, Norwood House, or Mr. Jas. Horton, Brayford, who are the Hon. Secretaries. The affair has been taken up with much enthusiasm by local photographers, and already close on fifty members have been enrolled, so that the Club bids fair to have a most satisfactory start in life. The Club has been founded for the study and practice of photography in all its branches, and is open to all taking an interest in "the black art," be they amateur or professional. Meetings are to be held twice a month during the season, and excursions are to be made during the summer months to various places of interest. The following constitute the officers of the Club:—*President:* Rev. Dr. Stott, Treswell.—*Vice-President:* Mr. Henry Mantle.—*Committee:* Messrs. W. J. Cant, T. Bell, Rev. Canon Fowler, B. Vickers, R. Slingsby, Asquith, G. Hadley, Birkbeck, and C. Smith.—*Hon. Librarian:* Mr. J. E. Dickinson.—*Hon. Treasurer:* Mr. J. M. Warrener, the Moorlands, Bracebridge.—*Hon. Secretaries:* Mr. W. R. Lilly, Norwood House, Lincoln, and Mr. J. W. Hortou, Brayford, Lincoln. We might state that the library has already been started, several books having been obtained. It is proposed to fix up a laboratory, with dark room, &c., for the use of the members.

Midland Camera Club.—April 22, Rev. J. Henry, F.R.C.S. (Vice-President), in the chair.—Being a Members' Lantern Night, there was a fair gathering of friends and visitors, including many ladies. Slides were shown by the following members:—Mrs. Welford, Dr. Maberly, Jevons Fowler, William Bentley, Rev. J. Henry, G. Warren, T. J. Perry, and W. D. Welford. Slides by John Carpenter (floral studies) and P. H. Fincham (Italian views) were also shown.

North Wales Amateur Photographic Society.—April 18.—A large muster of Llandudnoites and visitors assembled to witness the exhibition of a quantity of lantern slides, kindly lent by local slide-makers. They were shown by the fifty-guinea Beard's oxyhydrogen lanterns, recently purchased by Mr. Hughes, of Rochester House. This machine gives a brilliant and perfectly sharp image twenty-five feet in diameter. The slides were described by Mr. W. A. Whiston, genial Principal of the Llandudno Collegiate School. Some of the views and seascapes were the work of Mr. A. R. Dresser, Messrs. Gibson, of Hexham, and Lyd Sawyer, of Newcastle. Some twenty slides of local views were lent by Mr. I. Slater, of Mostyn-street, Llandudno. One view of Gloddaeth Hali is very fine indeed, and, in order to obtain it, Lady Mostyn had a lofty stage erected, under Mr. Slater's direction, for him and his camera. This is a hint to other patrons not to begrudge a few pounds when the expenditure will add to the beauty of the resulting picture. At Gloddaeth the gardens slope abruptly from the front of the mansion, and the erection was built of such a height and at such a distance that a rapid rectilinear lens would cover and include the whole building. This incident occurred during the visit of the Queen of Roumania to Llandudno eighteen months ago. The two dark rooms belonging to the North Wales Society at 44, Mostyn-street, are open daily for visitors till half-past ten p.m. Billiard and reading-rooms are adjoining, so that visitors can play while the hypo is finishing their plates. The dark rooms are fitted with Argand gas lamps, rose water-taps (*i.e.*, taps with a rose), hypo baths, and washing tanks. Plates and developers can be obtained at the counter.

Rochdale and District Photographic Society.—April 23.—The members of this Society had a very pleasant and enjoyable ramble to Hopwood Hall and Woods. After a short walk the grounds were reached, and the members at once set up and commenced work. Several plates were exposed on the old Hall itself, and the grounds and woods around also came in for a large share of attention, there being several very pretty and artistic bits. No difficulty was found in getting suitable subjects for the cameras. The Society has closed the rooms in Bury-road this week, and in future the meetings will be held in one of the local hotels, not yet decided upon. All correspondence must be directed to the Secretaries, W. and S. Ingham, 30, Freehold-street, Rochdale.

Correspondence.

☞ Correspondents should never write on both sides of the paper.

PERSONAL.—THE LATE HACKNEY EXHIBITION.

To the Editor.

Sir,—As we learn that it is the opinion of both yourself and Mr. Andrew Pringle that some remarks, appearing in our monthly trade circular, may be by others misconstrued to mean that we impeached your honesty and probity generally in regard to the judging at the late Hackney Exhibition, we should be pleased if you would do us the favour of publishing our sincere regret that any remarks should have so appeared that could even bear the semblance of such a meaning.

In our opinion, they cannot fairly be so interpreted, as, if they could, they would most certainly be untrue, and therefore would not have been published by us, as we know of no one who would even inwardly suppose that either of you would be guilty of any act that could be termed dishonest.—We are, yours, &c.,

Adams & Co.

81, *Aldersgate-street, London, E.C., February* 13, 1892.

[Although the above letter was addressed to us in a personal, as distinct from an editorial, sense, we accede to Messrs. Adams' request for its publication.—Ed.]

AN ACKNOWLEDGMENT.

To the Editor.

Sir,—I find that the Table relating to the sizes, pressures, capacities, contents, &c., of gas cylinders, given by me in the *Optical Lantern*, is the copyright of the Scotch and Irish Oxygen Company. I copied the Table, with slight alteration, from the *Indispensable Handbook to the Optical Lantern*, and acknowledged the source; but, as no statement is there made about copyright, I could not know that the Table was so protected. As, however, it is copyright, I gladly acknowledge the ownership.—I am, yours, &c.,

Andrew Pringle.

April 23, 1892.

"PHOTOGRAPHIC PORTRAITS."

To the Editor.

Sir,—I made a mistake in describing the publication which has gone out of its way to attack Mr. Maskell and Mr. Davison (the latter gentleman being now the recipient of one of those after-event apologies which serves merely to intensify the original insult)—I say I made a mistake in describing this publication as the trade organ of "opticians," and my thanks are due to Mr. Maskell for enabling me to rectify the slip. It has, of course, all along been plain, even to the casual reader only, that the paper is at the beck and call of *one* optician, whose fondness for newspaper controversy has more than once manifested itself in your own pages. In fact, an acquaintance with his style of writing even induces me to ask whether that gentleman himself did not actually produce the offending effusion, and if the leading article of April 21, in which your contemporary indulges in a little gas and high falutin' of the "We'll-stick-to-our-guns-to-the-last" style, and at the same time confers upon me the dubious honour of quoting and agreeing with some of my own remarks, does not exhibit indications of having also come from the master-hand which has lately bestowed so many remarkable things upon a grateful photographic public?

Mr. Maskell is unable to agree with me that this hostility to photography of the Indefinable School proceeds from the cause I assigned to it; I am sorry he cannot himself tell us what he believes it to be. Is he innocent enough to imagine that anyhody but an angry tradesman could be so alarmed over a few blurred photographs as to subsidise a newspaper to write them and their authors down? I should be glad to have Mr. Maskell's answer to that question. He flatters me in casting upon me the task of finding the grounds of excuse of the attack, an honour of which, however, I shall not try to deprive him. I regard it as calculated to perpetuate the practice of prostituting photography to the eccentric fads of the No-focus School to enter into any further argument with Mr. Maskell on the matter, and therefore I will ask him to let me leave him to find out (if he can) the cause of your contemporary's attack upon him and his friends. Of this, however, he may be sure—that, accepting the reason I have given, opticians generally, from what I can gather, so far from sympathising with the chagrin of one of their number, regard the productions of Mr. Maskell and his friends with mingled amusement and contempt.

Neither personally nor in print is Mr. Maskell a very amusing man,

and yet in his letter he has contrived to give me material for some good fun. Fancy him sitting down on Easter Sunday, pen in hand, wondering who on earth Cimabue Brown, jun., is, owning that he never heard of him before, and then "inclining to surmise" (only inclining) that "the name is a pseudonym!" Shade of Du Maurier! didst thou invent a Postlethwaite and a Cimabue Brown for this? But whether the pseudonym veils a distinguished identity or not is of little consequence, except in so far as it gives Mr. Maskell the opportunity of indulging in the stereotyped sneer at an anonymous correspondent. Perhaps Mr. Maskell himself supplies the best reason why opticians and others should in future treat Mr. Maskell and his friends with indifference, and that is that, numerically speaking, the new school is so small as to be beneath notice.—I am, yours, &c.,

CIMABUE BROWN, JUN.

April 25, 1892.

THE ACTINOGRAPH SPEED OF DRY PLATES.

To the EDITOR.

SIR,—In order to meet the wishes of numerous amateurs who desire to get the actinograph speed of plates of other make than our own, Mr. J. Sterry, of Earlswood-road, Redhill, has kindly consented to determine their speed by the Hurter & Driffield method, charging a small fee.

We speak from experience when we say we know this gentleman is thoroughly competent to undertake this testing.—We are, yours, &c.,

22 *and* 23, *Soho-square, London, W., April* 25, 1892. MARION & Co.

[We have also received a communication from Mr. Sterry to the same effect.—ED.]

"SPEED" OF PLATES.

To the EDITOR.

SIR,—As you are ever ready to lend a helping hand to the cause of photography, may I ask you to assist in (as public a manner as possible what is, or will shortly be, a desideratum to workers in the art?

Among those who have studied Messrs. Hurter & Driffield's system for obtaining correct exposures, there can scarcely be a second opinion as to the truth of their deductions; but the value of their discovery can only be fully appreciated by workers knowing the "speed" of the various brands of plates. To obtain correct exposure, which is the first essential towards a perfect negative, one must know four things—(1), the day and hour; (2), the focal length of lens and ratio of each separate stop; (3), the condition of the light; (4), the speed of the plate. This last element can best be determined by the maker of the plate. There must necessarily always be something left to personal equation, and in most other actinometers it is, in regard to the colour of a strip of prepared paper as acted on by the light, about the period of exposure. But the value of colour, it goes without saying, varies in different individuals in a most marked degree. This is not left to the individual's personal equation in Messrs. Hurter & Driffield's system. I have tried several actinometers, and find Messrs. Hurter & Driffield's unquestionably the most correct. I obtained my instrument from Messrs. Marion & Co., who, I notice, place on each packet of plates the correct speed of that particular batch. Other persons use other plates, and probably are as satisfied with their several plates as I am with mine. Could you not, *ex cathedrâ*, suggest to the various makers the advisability of indicating on each of their issues the "speed" as applied to the Hurter & Driffield's actinograph? To those who do not use that special instrument no harm could accrue; but to those who do it would prove an inestimable boon.—I am, yours, &c.,

Thurning Rectory, Oundle. J. CARTER BROWNE, D.D.

HOW TO AVOID THE MURKY SMELL OF THE OIL LANTERN.

To the EDITOR.

SIR,—It may be of great interest to many of your readers who use an oil lamp to know that the disagreeable smell so often experienced may be totally avoided by adopting the following precautions:—

When the lamp is done with, all the oil that can be got to run out should be poured off; then the wicks should be relighted, and allowed to burn right out. The lamp may then be put away.

It must not be charged with oil again till it is in position and about to be used, when no smell of any disagreeable character will be noticed.

By carefully adopting this method, what has been an unmitigated nuisance and deterrent to the use of the Sciopticon and other form of oil lamps will be avoided, and much pleasure experienced when showing the slides, where formerly annoyance and bad smells pervaded the exhibition.—I am, yours, &c.,

FRANK HOWARD.

Camera Club, April 25, 1892.

THE PHOTOGRAPHIC CONVENTION OF THE UNITED KINGDOM.

To the EDITOR.

SIR,—I take the liberty to request you to publish the following information about the Edinburgh meeting of the Photographic Convention in July next, which I believe will prove interesting to your readers, especially to those who are members.

Miss Catherine Weed Barnes, of New York, will read a paper on "Amateur Photography in America." Mr. Andrew Pringle will give an address on "Photography in Relation to Pathology." Mr. C. H. Bothamley has promised to give a fourth lecture on "Orthochromatic Photography." Mr. H. P. Robinson will also send a contribution on "Individuality in Photography."

Other papers have also been promised, and I will send you a further communication on the subject.—I am, yours, &c.,

F. P. CEMBRANO, JUN., *Hon. Sec.*

10, *Cambridge-gardens, Richmond, Surrey, April* 25, 1892.

A NATIONAL PHOTOGRAPHIC RECORD SURVEY.

To the EDITOR.

SIR,—As I have to read a paper—*Proposal for a National Photographic Record and Survey*—before the Photographic Society of Great Britain on May 10, may I ask secretaries of societies, or any individuals who have commenced survey work, and with whom I have not been in communication, to kindly send me details as early as possible, so that I may be able to give them due credit and publicity.—I am, yours, &c.,

Birmingham, April 25, 1892. W. JEROME HARRISON.

DEVELOPMENT ON THE SCREEN.

To the EDITOR.

SIR,—I have always used the ferrous oxalate for this experiment, owing to its being so non-actinic. Pyro or hydroquinone would, no doubt, do if a yellow glass were interposed between the light and the plate. No doubt, also, one of the very slow bromide lantern plates could be used instead of chloride.

I have not tried, but would suggest, as possibly a pretty experiment, to bleach a chloride plate with mercury and then redevelop with hypo. Could not a carbon transparency be used? The gradual dissolving of the soluble gelatine would be seen very well.—I am, yours, &c.,

The Hut, Ingatestone, April 25, 1892. H. G. M. CONYBEARE.

PRINTING-OUT CHLORIDE PAPER.

To the EDITOR.

SIR,—Would not paper that was to be used for printing out require to be very kept from white light? In the process of manufacture it is not improbable that paper which the manufacturer expects will be printed out may be exposed to enough white light to render it useless for development.—I am, yours, &c., Q.

Deal, April 21, 1892.

[We have a leading article on the subject elsewhere. Probably the exposure the paper undergoes in the manufacture would not interfere with its developable properties.—ED.]

EXHIBITION AT BATH.

To the EDITOR.

SIR,—Permit me to draw attention to the enclosed projected show of photographs and apparatus to be held in May next. Contributors will be permitted to affix name and title on their work, and, if professional, the price. No entrance fee, no award, no costs of carriage.

The Sub-Committee appointed by the Bath Photographic Society are working in earnest, and the experiment is regarded as one highly probable to succeed and, in time, to increase in usefulness. Already many well-known amateurs have promised to contribute, and the manufacturers will be well represented.—I am, yours, &c.,

W. M. ASHMAN, *Hon. Secretary Bath Photographic Society.*

12A, *Old Bond-street, Bath, April* 20, 1892.

[The following are the particulars.—ED.]:—

FLORAL ART AND INDUSTRIAL EXHIBITION, BATH, MAY 18 AND 19.

SECTION B.—(Art Department). Photographic Exhibits.

Amateur: 1. Views; 2. Genre; 3. Flashlight Photography 4. Scientific; 5. Lantern Slides. *Professional:* 6. Portraiture; 7. Enlargements; 8. Views; 9. Lantern Slides; 10. Apparatus of recent introduction; 11. Early Specimens of Apparatus and Photographs; 12. Other Exhibits of interest besides those above mentioned.

Exchange Column.

Answers to Correspondents.

All matters for the text portion of this JOURNAL, *including queries for "Answers" and "Exchanges," must be addressed to* "THE EDITOR," *2, York-street, Covent Garden, London. Inattention to this ensures delay. No notice taken of communications unless name and address of writer are given.*

*** *Communications relating to Advertisements and general business affairs must be addressed to* "HENRY GREENWOOD & Co.," *2, York-street, Covent Garden, London.*

PHOTOGRAPHS REGISTERED:
T. S. Lisson, Westmoreland.—*Photograph of Deer in Leven's Park.*
James Downey & Sons, South Shields.—*Photograph of Mr. John L. Richmond.*

J. H. HARVEY (Melbourne).—Your suggestion shall be considered.

W. E. C. B.—The cause of the spots is imperfect fixation of the prints.

OPAL.—Messrs. Morgan & Kidd, we believe, supply bevelled opals to the trade.

PLATINIC.—There is no metal recoverable that would repay for the trouble involved.

J. C. P.—The quantity of pyroxyline should in both cases be twenty-five grains. The emulsion would be suitable for opals.

SYPHON.—If you mean Mr. Buchillot, the address is Southampton-row. The address of the Autotype Company is New Oxford-street, W.

JOHN STERRY.—Thanks. As you will perceive from our correspondence columns, we have already received a letter from Messrs. Marion on the subject.

A. G. BRADY.—The primuline process is patented, but no doubt you can obtain a licence to work it. Write to Messrs. Green, Cross, & Bevan, 4, New-court, Lincoln's-inn, W.C. The materials are not expensive.

W. SHERRELL.—If you will refer to pages 322 and 337 of the volume of the JOURNAL for 1891, you will find two articles treating on the addition of sal ammoniac to the developer, which will give you the information you desire.

S. A. W.—If a photographer supplies bromide prints for platinotypes, he is committing a fraud upon his customers quite as great as the man who supplies margarine for butter, and brings himself within the pale of the law if the customer chose to take action.

COPYIST.—The formulæ for orthochromatising plates given in the ALMANAC are amongst the best that have been published. You may certainly rely upon what Mr. Bothamley has written on orthochromatic photography generally. There is, as you remark, plenty of room for further experiment.

TOURIST.—If you intend to travel with your camera anywhere on the Franco-German frontier, you should certainly provide yourself with a passport. You must bear in mind, however, that the possession of one will not protect you from inconvenience if you set up your camera in the neighbourhood of any of the forts.

PRINTER writes: "Would you kindly tell me if silver prints, placed in a solution of sulphuric acid after fixing, are rendered less likely to fade? and, if so, what strength the acid bath should be, and how long the prints may remain in it?"—If fugitive prints are desired, the proposed treatment would be one of the best methods of producing them.

C. BENTON writes a long letter in which he attributes the entire cause of fading to the deleterious cards upon which the prints are mounted, and contrasts them with the cards that were used thirty years ago. Doubtless some mounts have a very destructive action on the prints put upon them, but it is useless to argue that the mounts are the sole cause of the fading of silver prints. If it were, then all unmounted prints should be permanent. Are they?

J. T. C.—Although a portrait lens is the quickest in action, it is not the best to use in taking a group of a hundred or more people, on a 12×10 plate, out of doors. In order to secure good definition in the different planes, and sharpness to the edges of the plate, it must be considerably stopped down, so that its rapidity becomes reduced to that of, say, one of the "rapid" type, without any corresponding advantage. Indeed, the latter will be found the better instrument of the two, in practice, for that class of work.

C. RAY.—None of the well-known dry-plate makers will purchase old negatives for the purpose of cleaning off the films and recoating the glass. The only way we can suggest of dealing with them is to pay the dustman to take them away. You might, however, clean off the films with the view to recovering the silver from them, and then disposing of the larger-size plates to some nurseryman for glazing greenhouses; but whether this would recoup you for the time and trouble involved you are better qualified to form an opinion than we are.

"PHOTOGRAPHIE," who wishes to know the best camera and stand, half-plate size, for travelling with to take views, and to be also used for indoor work, photographing samples of goods, and which lens we consider the best for both purposes—in fact, complete kit, and the price—and also asks us to say which we consider the best and quickest developer, disregards our rules in not enclosing his (or her) name, and, if a reader of our pages, should know that we always decline to say which we consider the "best" camera and the "best" lens.

R. W. says: "The other day I took the interior of our parish church. It is a very dark one, as most of the windows are of stained glass. I gave it an exposure of half an hour, and it is fully done; but the extraordinary point in connexion with the picture is, that in one of the corners there is, on a plain piece of wall, a window that is on the other side of the building, and could not be seen on the focussing screen when the camera was replaced in precisely the same spot the next day. Can you suggest any reason for this strange phenomenon?"—The explanation is very simple: There is a minute hole in some portion of the camera or the bellows, and that has acted the part of a "pinhole camera."

H. WILLETT writes: "Shall be glad if you will inform me what the law is as regards exhibiting of specimens. Can a person compel a photographer not to exhibit a photograph? Is there a law to make him take it in from case?"—Whatever may be the state of the law on the point, a photographer has no moral right whatever to exhibit a portrait without the sitter's permission. If a portrait is shown to the annoyance of a sitter after a formal notice for its removal has been served, no doubt an injunction to restrain could be obtained; then the photographer might be mulct in heavy costs. In one case a sitter took the law into his own hands, and smashed the portrait and case, and was summoned for it. The judgment was, if we mistake not, that he was justified in destroying the portrait, but he had to pay for the glass, and the photographer lost his costs.

S. W. writes: "Two years ago I took an apprentice, with a premium, for three years. The friends of the youth now complain that I am not thoroughly teaching him the business, and are threatening me with legal proceedings for the recovery of the money and services rendered. They say that I should teach him such processes as wet collodion, carbon printing, enlarging by different methods, retouching, taking landscapes, &c., things I do not do myself. Is this reasonable?"—Yes. If you have taken a premium, and engaged to teach the youth photography, he is quite entitled to be taught these and other things in connexion with the business. If you took the money only to teach him how to take a negative and print from it in silver, such should have been stated in the indentures. Unless this was done, those who paid the money have good ground of action, and will, doubtless, recover.

F. HALL writes: "I want to convert some silver sulphide into pure nitrate Can you kindly tell me how I can do it without the aid of a fire? By this I mean by a process without fusing, or any process of that sort. In looking the subject up, I see there is an article on it in the JOURNAL of June 7, 1889, in which it says that it can be dissolved in pure nitric acid. I have tried this, and find it will not dissolve to any extent; also the little that is obtained is not pure, but mixed largely with impurities. I want the nitrate for experimental purposes and for a wet-plate bath. If you can help me, I shall be very much obliged."—If the directions as given be carefully followed, nitrate of silver will be obtained; but, if *chemically* pure nitrate be required, instead of crystallising the nitrate first obtained, the silver should be precipitated from it as a chloride. The chloride then, after thorough washing should be decomposed by pure zinc and sulphuric acid, washed, treated with sulphuric acid to remove any undissolved zinc, again washed, and the pure silver thus obtained dissolved in nitric acid and crystallised. The simplest and most economical plan is to send the sulphide to the refiner, and get from him in exchange either nitrate of silver or cash.

LONDON AND PROVINCIAL PHOTOGRAPHIC ASSOCIATION.—May 5, *Wet Collodion*, adjourned discussion. 12, Members' Open Night. 19, Monthly Lantern Night.

WE are happy to announce that Mr. F. E. Ives, of Philadelphia, has arrived in this country, and on May 10 and 17 lectures at the Royal Institution on *Photography in the Colours of Nature*.

PHOTOGRAPHIC CLUB.—May 4, *Hand Cameras up to Date*. 11, *Fancy Printing and Mounting*. Outing, Saturday, April 30, to High Beach. Train from Liverpool-street for Loughton, 2.35.

ON Tuesday, May 17, Mr. A. W. Dawson gives a demonstration on *Photogravure* before the Photographic Society of Great Britain. We understand that on this occasion a large number of prints will be on view in illustration of the process.

FROM the London Sensitised Paper Company we have received a small sample of their "Sans Egal" sensitised paper, which, upon trial, we find to print quickly and tone easily, in the ordinary acetate bath, to a most agreeable warm colour.

SOUTH LONDON PHOTOGRAPHIC SOCIETY.—May 2, Demonstration in *Carbon Printing*, by the Autotype Company. 7, Excursion to Greenwich. 16, *Stereoscopic Photography*, by W. I. Chadwick, Manchester. 21, Excursion to Loughton for High Beach.

MESSRS. PERKEN, SON, & RAYMENT ask us to state that, having entirely sold out the third edition of the *Beginners' Guide to Photography*, which completed the twenty-fourth thousand, they are just issuing a fourth edition of the usual number, 8000. It is to be sold, as usual, cloth covers 6*d*.

AN amateur photographic exhibition will be held at Castle Wemyss on the 27th and 28th of May, 1892. Section I. is open to amateurs who have photographed under two years from June 1, 1892. There are two classes:—(1) Portrait or Group, any process; and (2) Landscape or Seascape, any process. Section II. is open to all amateurs, and there are seven classes as follows:—(1) Portrait or Group, any process; (2) Landscape or Seascape, $8\frac{1}{2}\times6\frac{1}{2}$ and over, any process; (3) Landscape or Seascape, 8×5 and under, any process; (4) Instantaneous, any process; (5) Animal Study, any process; (6) Enlargement, any process; (7) Lantern Slides, any process (set of six). All entries must be made to Miss Burns, Castle Wemyss, Wemyss Bay, on or before May 20.

PLATINOTYPE MODIFICATIONS.

The latest modification of the platinotype process is so very simple in practice that we can perfectly sympathise with several experienced platinotype printers who have remarked, almost in a spirit of complaint, that platinotype has now been made too easy. This feeling on the part of trade printers and others is not difficult to realise when we consider that Mr. Willis, in the latest outcome of his experiments, has not only swept away at a stroke sundry difficulties of working attendant upon the hot-bath process, the popularity and advantages of which remained undiminished by the cold-development, platinum-in-the-bath paper, which was brought out in 1888, but has also imparted to the sensitive coating a variety of useful properties, which reduce to the minimum the chances of failure arising from imperfect manipulation of the paper. In brief, the new paper, so far as quality of result is concerned, entrusts so little to the skill of the printer, as compared with the hot-bath process, that it may be seriously questioned whether the art of printing from the negative in platinum is capable of undergoing any further simplification at Mr. Willis's hands.

The old cold-bath process attracted little favour on account of the uncertain qualities of the pictures it produced, and the difficulty of arriving at the causes of the failures, with a view to their prevention. Mr. Willis has indicated some of the causes which tend to produce this uncertainty in cold development. The rate of solution by the developer of the soluble salt on the paper, he points out, must not bear too large a ratio to the rate at which the pigment-forming salt is reduced. If the salts on the paper were dissolved before any reducing action commenced, no image could be formed, and, on the other hand, if there were only a small portion of undissolved salt on the paper at the moment of development, the image formed would be weak. Temperature governs both the rapidity of reduction as well as the rapidity of salts on the paper, and, as these rates do not vary according to the same law, there are, as Mr. Willis further says, two factors to be dealt with. The ratio which these two velocities bear to one another at a given temperature governs the results obtained. In the new paper, to quote Mr. Willis again, rapidity of solution of the salts does not overtake rapidity of reduction, and thus the image is developed before the image-forming salts are removed from the paper.

Within the last few weeks we believe experience of the new paper has not only confirmed some of the original claims made on its behalf, but has also admitted of others being urged. For example, Mr. Willis laid down the temperature of development at from 50° to 70° Fahr., but we gather that it has been found practicable to use the bath at a temperature as low as 40°. When we add that, at a normal temperature, development takes some thirty seconds or so before starting, and that the developing solution employed need not differ in composition or strength from that used with the hot-bath process, we have indicated the cardinal points of difference from, and resemblance between, the two processes, the details of the preparation of the new sensitive surface, of course, not being available. But nobody's curiosity on this point will, we conceive, outlast a feeling of thanks to Mr. Willis for having relieved the platinotype worker of the spirit lamp, the thermometer, and the iron dish.

As to the qualities of the pictures yielded by the new method, we have satisfied ourselves that in fineness of deposit, in crispness of detail, in vigour and depth of shadow, and in range of tones, the cold-bath paper has the best of the comparison with the hot bath. There is, indeed, a uniform richness of deposit throughout the scale, which was often sought for vainly in prints produced by hot development—the latter sometimes having a flatness and slatiness of tone not always referable to errors in exposure or development. As to the former class of errors, with the new paper Mr. Willis has, we suppose, modified his original ideas. At the outset he recommended hypophosphite of soda as a restrainer in over-printing; in practice, however, simple dilution of the developer answers admirably, while, with under-printed proofs, heating the developing solution provides a remedy.

But it is in respect of those properties of the sensitive compound to which we have made allusion above that we think the new paper possesses a peculiar value. It is, so to speak, far less tender to the touch of accidental ill treatment than the surfaces it has displaced, and on that score it is assured of a freer welcome in the printing room than they. Air bubbles, if they form, do not leave any mark behind, and indeed, to push this property to a critical extent, the paper may be developed in sections, and when the entire print is finished it presents an appearance of homogeneity inconsistent with the method of its development. Again, accidental finger-marks, when made with the developer in the undeveloped print, do not show after development. The "unbreakability" of the surface is proved by the fact that a fold in the exposed paper leaves after development no visible mark. Finally, but not to exhaust the list, development may be accomplished as easily and as efficiently by a brush as by flotation, a fact which we are inclined to think may, in skilful hands, be taken advantage of in the production of artistic results from inferior negatives not otherwise within reach.

It will be seen that the latest advance in platinotype printing is a distinct and welcome one. That it will tend further to popularise a beautiful and favourite process we have little hesitation in conjecturing. It has left Mr. Willis no more worlds to conquer, but it has earned him the thanks of all

lovers of platinotype printing. We do not know whether paper giving sepia tones is amenable to cold development; if so, we await its appearance with interest, inasmuch as, in the present ascendency of warm tones, sepia-toned platinotypes by the new cold-bath process should be very popular.

THE EMPLOYMENT OF STOPS IN LANDSCAPE WORK.

The landscape photographer of to-day works under very different conditions, both as regards lenses and plates, to his congener of twenty years ago; but it may be seriously questioned whether, taking into consideration the great improvements that have been made in his instruments and materials, he surpasses or even equals the best work of that period. The only, or, at any rate, the chief advantage those improvements have had for the modern worker, in too many cases, has been that he is enabled with less trouble and effort to produce fairly good work, whereas his predecessor was compelled to exercise every care in, and devote no small amount of intelligence to, the proper carrying out of his various operations.

Looking to the optical side of the question, one cannot but be struck by the vast difference that exists between the instruments in common use at the present time and those that were almost universally employed even as late as only twenty years back. No photographer—except those who are satisfied with the very cheapest of apparatus—now feels himself properly equipped unless he is armed with a lens of the "rapid" type, and these, of very excellent quality, are obtainable at comparatively reasonable prices. But at the period referred to, although such lenses in various forms were in existence, their high price deterred the majority of workers from giving up the single landscape lens with which they had been so long familiar, and few amateurs, or even professionals, except such as made landscape work their sole business, employed any but the old favourite.

In those days of long exposures—for even the relatively small number of wet-plate landscape workers were badly handicapped in comparison with their modern brethren—the cry was for optical improvements, and this in spite of the rapid form of lenses that were already available. These, it is true, were usable under certain conditions with a far larger working aperture than was possible with the single lens, but it was at the cost of diminished depth of focus and general covering power; and the landscape workers of that day declined to relinquish quality of result for mere rapidity of working.

Now, on the other hand, the tendency is rather in the opposite direction, and the modern amateur is all too prone to utilise to their utmost the vastly increased powers placed at his disposal, to the almost total disregard of results. Thus we find many amateurs who would no more think of going out for a day's landscape work without an instantaneous shutter than of leaving the lenses at home, and who would scarcely feel happy unless their plates were of the most rapid kind. It has been so frequently pointed out that, though it is an invaluable power to be able to make drop-shutter exposures when circumstances compel, still it is in the highest sense foolish to make a practice of doing so indiscriminately. We have seen many amateurs at work on foliage subjects, with the shutter, or "off-and-on" cap exposures, but we can truly say we never saw a really good result therefrom, that is to say, a result that would not have been greatly improved in some or all respects by a longer exposure. The Shakesperian proverb says truly, "'Tis well to have a giant's strength, but 'tis tyrannous to use it as a giant."

There are several arguments that might be brought forward by the old time landscapist in favour not so much of long exposures as of using the stop in preference to the full aperture of the lens. The one is, of course, a concomitant of the other, but not even the strongest partisan of "old times" would preferably give five minutes, or even five seconds, exposure if an equally good result could be got instantaneously. But there are advantages accruing from the use of the stop that possibly many modern amateurs have never thought of.

One function of the stop, or rather the one supposed objection to its use—that is, of course, an unnecessarily small stop—in former days, was that it destroyed atmosphere and distance. Now, though practically, in employing a very small stop, the general tendency to want of atmosphere might be greater than when a larger aperture was regularly used, we are personally of the opinion that it was not the fault of the stop as such, but the stronger aptitude to under-expose that its use involved. Less attention was paid formerly to the accurate relation of the exposures made with different stops, and, as every one is aware, there is a very strong inducement to make a long exposure as short as possible; hence we think that, when using small stops, the want of "atmosphere" came to be set down erroneously as a necessary function of the stop instead of to an unconscious habit of under-exposure.

The landscape worker of old laid himself out to produce a picture as optically perfect as his instruments would permit, and strove to have both his foreground and distant objects, the central as well as the marginal, as well defined as possible, and to attain this end he stopped down his lens as much as the rapidity of his plates would allow him to do conveniently. The "impressionist" school have done much latterly to cast ridicule upon the idea that want of sharpness constitutes "art," or that it increases the "softness" of a picture. The idea of giving prominence to the chief object in a picture is an excellent one, but it should be carried out in other ways than by making that one object sharp, and all the rest out of focus. Again, the argument that in nature the eye only sees a small portion of the landscape distinctly (or sharp) at once is quite true; but it can see any portion sharp that it is turned to, which is more than can be said of the impressionist's work, in which, if the eye be taken off the main object, there is nothing sharp to see.

Let us, by all means, then, start with a well-defined picture, for, however microscopically sharp it may be, if the gradations of light and shade are correct, that is to say, if it has been properly lighted and exposed, the minute definition will in no case prove offensive. Where such appears to be the case, it will generally be found due really either to bad lighting, or to too harsh contrasts. We remember, many years ago, a charming picture by an amateur friend, of the Matterhorn, and the well-known Rosenlaui Valley, which would have been perfect but for such an effect. In one portion of the picture is a belt or mass of dark pine trees, and these were almost microscopically rendered, being at the same time lit by a strong side light. The result was that the extremely fine rendering of the illuminated side of the trees, sharply cut against the deep shadow, gave the trees the appearance of being cut out of paper, the result being set down to excessive sharpness, whereas, in our view, it was solely due to the exposure having been insufficient for that portion of the picture.

Now, with the best of lenses, of whatever form, it is perfectly well known that objects at widely different distances cannot be secured of equal sharpness when the full or a large aperture is employed, because the lens is then deficient in what is known as "depth of focus." Neither, under similar circumstances, will a lens of the focus intended to cover a given sized plate do so equally from centre to edge on account of the natural curvature of the field, and in both cases a stop becomes a necessity. In the latter instance, a lens of much longer focus, and capable, therefore, of covering a larger surface, may be used to get over the difficulty of curvature of image, if the subject will admit of it; but then, in the matter of depth of focus, things are worse than with a shorter-focussed lens. Wherefore we say, Use a stop, and be content with a moderate exposure.

But, from another point of view, a somewhat protracted exposure becomes an absolute advantage, notably on a windy day, paradoxical as it may appear. Here rapidity of exposure would seem to be the one essential, and certainly, if the quality of result could be obtained with an *instantaneous* exposure, nothing better could be desired. But, as we have said, drop-shutter exposures will *not* give the result, and, failing that, an exposure of half a second, or one, two, or three seconds will be far more likely to show motion of the trees than one of ten, twenty, or thirty. Look over a collection of landscapes of twenty years or more ago, more especially if taken on dry plates requiring exposures, perhaps, of half an hour, and note how very favourably the rendering of the foliage, as regards stillness, compares with much of the work of to-day executed in a second or two. Now we have too frequently to accept a fan-like blur as representing a hanging spray, or, in bad cases, a series of concentric segments of a circle will mark the line of motion of a swinging branch.

In very few portions of the country where landscape work is worth doing is a perfectly still day ever experienced, or, if it should be, it is under circumstances of light that render work impossible. The regular landscape worker knows this, and goes prepared to "dodge" the wind, selecting those moments when the foliage is still for an instant, and making his exposure in little bits. It was no uncommon thing in old dry-plate days to spend half an hour or an hour in thus eking out an actual exposure of two or three minutes. Now, failing an instantaneous exposure, a merely short one is useless, except to show that the trees were in motion when it was made. To cut up a total exposure of two or three seconds into fragments is a practical impossibility; but, if by inserting a stop the necessary time can be increased to, say, ten seconds, there is a chance, by means of manual dexterity and closely watching the foliage, to divide the time into small portions during which the wind is absent. For this purpose a simple flap shutter, worked with the thumb and finger, is more convenient than the cap, and is further useful as a sky shade.

We might enlarge to almost any extent on the desirability of using the stops instead of full aperture, but space will not permit; we have, however, said enough to warn our younger readers of the folly of going in for quick exposures instead of studying quality of result.

Photography in Natural Colours.—*Apropos* of Mr. F. E. Ives' lecture on *Photography in the Colours of Nature* at the Royal Institution next week, we understand that M. Lippmann, of Paris, will shortly announce the results of some further experiments in the direct reproductions of colours. The methods of both workers are, however, as our readers are aware, entirely dissimilar.

The "Daily Chronicle" on Process Work.—Our morning contemporary of the 4th inst. devotes a large portion of its space to a review of the month's illustrated periodicals, chiefly with regard to the methods of reproduction selected. Of many of the photo-mechanical blocks in the last *Harper* we are told that "these reproductions prove that the cheap sneers at cheap processes can henceforward only be indulged in by people who do not know what they are talking about." Of another magazine, however, it says that it thinks "it can almost dispense with the artist and substitute for him the photograph." Query, "photographer?" "That it fails lamentably in doing this is because photography is not a fine art, and therefore the reproduction of a photograph is not an artistic object." Good reviewer, there are other people who do not know what they are talking about besides those who fling cheap sneers at cheap processes.

Mineralised Methylated Spirit in Collodion Emulsion.—At the last technical meeting of the Photographic Society of Great Britain some stereoscopic collodion transparencies by Mr. Warnerke were shown, the halves being made from different emulsions coated on the same plate. The one emulsion was made with the old form of methylated spirit, the other with the mineralised compound. Mr. Warnerke claimed, and a comparison of the results seemed to support the claim, that the emulsion made with the mineralised spirit was more sensitive than the other, without any disadvantages to set against this gain. The images, however, were, as was pointed out at the meeting, decidedly foggy—too foggy, in fact, for lantern-slide work. On the whole, however, the new methylated spirit, from this and other evidence, does not appear to have the deleterious effect in collodion emulsion work that was anticipated. Of its effect in gelatine emulsion making we are without any data.

The Society's Meetings.—The lecture on *Photogravure* which is to be delivered by Mr. A. W. Dawson at the Photographic Society of Great Britain on May 17 is an "extra night," that is to say, the meeting will be in addition to the technical and ordinary meetings which are held every month. We do not doubt that, to employ the trite phrase, the lecture and its illustrative examples will be very interesting, and we hope a good attendance will result. But our hope is unaccompanied by a feeling of confidence in its realisation. The attendances at the Society's special lectures earlier in the year were ridiculously small, and at the technical meeting on the 26th ult. the amazing number of nine members climbed up those awful stairs in Great Russell-street. What is the cause of this apathy among the members? A suburban Society, the North Middlesex, frequently has an attendance of from forty to fifty; the London and Provincial invariably makes a good muster; and the Photographic Society of Great Britain—the "Parent" Society—never!

Speed of Plates.—Dr. Carter Browne, in our last issue, asks us to suggest to plate-makers the advisability of indicating on each of their boxes of plates the "speed" as applied to the actinograph of Messrs. Hurter & Driffield. We are pleased to endorse our correspondent's suggestion, the more readily as we have for years past urged makers to adopt a reliable and common method of indicating the rapidity of the plates they send out. It is well known that the sensitiveness of an emulsion, as determined by Mr. L. Warnerke's sensitometer, cannot be relied upon for comparative purposes, a circumstance which, to our knowledge, has induced many of the makers to relinquish its use. We are aware that several of them prefer to test the speed of their plates in the camera, but this is for their own information and not for that of those who use the plates. The terms makers employ for distinguishing the various rapidities of their plates are not only meaningless and misleading, but are absolutely useless for purposes of comparison both in practical and experimental work.

Action of Ammonia in Development.—In the course of his long and abstruse paper on *The Theory of Development*, which was read at the Camera Club Conference, Professor H. E. Armstrong

F.R.S., after pointing out the solubility of silver bromide in ammonia, suggests that, in developing with the aid of ammonia, the image is in part formed from silver in solution. We also gather that, in his opinion, it is due to the solvent power of ammonia that with a pyro-ammonia developer peculiar kinds of fog are produced. It is a moot point whether the ammonia really plays the part which Professor Armstrong assigns to it, and certainly, to our knowledge, it has never been demonstrated by experiment. Negative evidence, however, may be drawn from some remarks by Mr. Bothamley, in his paper read at the same Conference (see page 264, *ante*). That gentleman's experiments, made to ascertain "whether ammonia solutions of the strength commonly used in developers do really dissolve an appreciable quantity of silver bromide from a gelatino-bromide plate," proved "that the quantities dissolved were so small that it is difficult to regard them as playing any important part in the production of fog." If this was the conclusion reached after the ammonia solutions of various strengths had been allowed to act on the films for forty-eight hours, what is the likelihood of the image being partly formed of the "silver in solution?"

OBSOLETE PROCESSES.

No. 1.—The Daguerreotype.

The majority of photographers, who have only taken up the practice of the art during the last one or two decades, have very little idea of the practical details of many of the older processes. Therefore it may be desirable to describe some of those which were in general use in the earlier days, and by which excellent results were produced. It is obviously impossible, in a single article—or, indeed, in half a dozen articles, even were the space at disposal—to go into the minutiæ of the working details of the different methods, and the modifications thereof—the causes of failure, the remedies, and the like. Our object will be gained by briefly describing the processes as they were generally worked at the time of their abandonment; that is, with all the improvements up to the then date.

The Daguerreotype, as all our readers are aware, is a picture on a silvered copper plate. It is, or rather was, and we shall write in the past tense, essentially a dry process, in fact, more so than any modern one, inasmuch as the plate was not touched with water until the fixing operation. The plates were supplied ready plated with a substantial coating of silver, and with a perfectly even surface. But most of the best operators preferred to supplement the plating with a layer of *pure* silver by the electrotype process, a voltaic battery being an adjunct in every well-appointed Daguerreotype establishment.

One of the most important operations in the Daguerreotype process was that of polishing the plate. Unless this was perfectly performed, a first-class picture was an impossibility. The plate, after having its edges bent slightly backwards, so as not to cut the buffs presently to be described, was first treated with very fine tripoli and alcohol; at one time olive oil was used. It was applied on cotton wool with a circular motion. Then it was polished with dry tripoli on fresh cotton wool, this time in one direction only—usually the longest diameter of the plate. After this, it was ready for buffing.

The buffs were flat pieces of wood, about three inches wide, and twelve or fifteen inches long, with a handle at one end. Sometimes they were slightly convexed, lengthwise. The wood was first covered with one or two layers of cloth, or wash-leather, tightly strained on, and then with good cotton velvet. The plate, already polished with the tripoli, was now clamped to a holder, fixed to the table, and dusted over with the finest rouge, and then polished with one of the buffs, always in the same direction. Next it was dusted with finely powdered charcoal, or lamp-black, free from grease, and buffed again, separate buffs, of course, being kept for each of the polishing powders. Necessarily the greatest care had to be taken that not the slightest particle of grit reached the plate or the buffs, as it would produce a scratch which could only be removed by going through the whole of the operations afresh. The surface, when polished, was no longer white, but black. The finer the polish the blacker it was.

The next operation was that of rendering the surface sensitive to light. This, as a matter of course, had to be done in the dark room. The iodine and bromine box was a long, oblong wooden box, divided across the middle by a partition. Each compartment held a deep glass dish, the one for iodine, and the other for bromine or the accelerating agent. Over the pans were fitted sliding glass plates, which covered them up, so as to prevent the escape of vapours when the box was out of use. In the front of the box were a couple of small doors, fitted with looking-glass, so that the operation of sensitising could be watched as it proceeded. In one pan were placed some crystals of iodine, and on it some cotton wool. In the other was put some bromide of lime. The object of the wool was to evenly diffuse the vapour. The plate was placed in a frame something like the carrier of a dark slide, which could slide alternately over one pan or the other. It was first exposed to the iodine until it acquired a deep golden tint, as seen in the looking-glass, by the formation of iodide of silver. Then it was slid over the vessel containing the bromide, where it was allowed to remain until it became of a deep brown. Next, it was passed back again over the iodine. Here it now quickly began to assume a rose tint, when it was removed. It was then ready for exposing in the camera, and the sooner the exposure was made the better. Considerable experience was necessary in the sensitising in order to secure the plates in the best condition.

The exposure with a Petzval portrait lens, which then had an aperture of *f*-5 to *f*-4, in the studio, with a tolerably good light, was from five to thirty seconds.

The image, it need scarcely be mentioned, was latent. For its development a "mercury box" was required. That consisted of a box, mounted on legs, at the bottom of which, and protruding through it, was a small iron cistern, to contain mercury, and a thermometer, with its bulb in the cistern and the index tube outside, so that the temperature could be read without opening the box. The exposed plate was placed in the box, some distance above the mercury, at an angle of 45°, and the lid closed. A lighted spirit lamp was next placed under the cistern, and the mercury heated to from 140° to 160° Fahr. In a few minutes the fumes of the mercury caused the image to gradually make its appearance, the development being watched through a small glass window in the front of the box, by the aid of a taper. When judged to be sufficiently developed, the plate was removed. For the development it was essential that the mercury should be pure and free from oxidation. Up to this point it will be noted that the plate has not been touched by water.

The next operation was to fix the picture. This was done by first plunging the plate in a dish of water, and then immersing it in a weak solution of hyposulphite of soda, about one part of the salt to sixteen of water, until the yellow colour disappeared, as in the case of fixing modern plates. It was then well washed and finally rinsed with distilled water. Some operators used to flow a little alcohol over the developed plate prior to placing it in the water, and then the solutions took more readily to the surface. Although the picture, so far as the action of light is concerned, was fixed at this stage, there was yet another operation to be gone through, sometimes called fixing that of "gilding" the image.

This was done by placing the plate on a levelling stand, and covering it with a solution of *sel d'or*—the double salt of hyposulphite of gold and soda. It was then heated with a spirit lamp from below, when, in a minute or two, the image increased considerably in depth and brilliancy, while its permanency was greatly enhanced. Indeed, a well-gilded Daguerreotype may still be reckoned the most permanent of all silver pictures. After gilding, this was washed with distilled water and dried.

The drying of the plate was not an unimportant matter, for, unless it was carefully done, the beauty of the picture might be greatly marred; the mode was this. After well rinsing with distilled water—ordinary water would produce markings—the plate was held in a pair of pliers and drained from one corner, while the gentle heat from a spirit lamp was applied to the opposite one. The plate was then slowly raised without altering its position, so that the evaporation proceeded regularly. If the drying, when once commenced, were arrested, a mark would be produced on the image that was exceedingly difficult to get rid of.

CONTINENTAL NOTES AND NEWS.

Fixing Negatives Temporarily.—For this object, M. H. Reeb advises that the negative, when removed from the developer, be drained (not washed), plunged into a two per cent. solution of tartaric acid, and left therein for from half a minute to a minute. The operation is then finished, and the negative can be exposed to diffused light with impunity, and is then washed and dried. Of course, such a method would only be of use to the photographic tourist, who might find it advantageous to defer fixing until his return home. Any developer except iron is permissible.

A Novel Reducer and Intensifier.—Herr Lainer, in the *Rundschau*, suggests a method for reducing over-dense, or clearing yellow-stained, negatives, which, however effective it may be, certainly does not err on the side of rapidity. It is to immerse the *cliché* for from six to twelve hours in a bath of soda hyposulphite strongly acidulated with sulphuric acid. We see nothing in the more expeditious processes which should induce us to desert them for this. In the same journal another gentleman recommends the intensification of thin negatives by first of all soaking the plate in water, and then immersing it in a solution of carmine. It is best to have a weak solution of the latter, as the operation can be repeated.

To Recover Gold from the Sulphocyanide Bath.—When using the sulphocyanide toning bath, says the journal quoted, the gold may be very easily recovered by adding to the used bath a small quantity of hydrochloric acid and sulphate of iron. This throws down a precipitate of metallic gold mixed with hydrated oxide of iron. The mass is dried, and the iron removed by heat.

The Fathers of Photography.—Señor Fernandez, of Barcelona, has been writing to the French photographic papers, stating that he is about to construct a large hotel and studio on the spot where the first Daguerreotypist first "took the cap off." He intends to have the portraits and names of Daguerre, Niepce, Poitevin, Boyar, Talbot, Arago, and Laborde, also views of the places where they lived, included in the decoration of the façade of the buildings, and he asks the assistance of the press in the matter. The *Revue de Photographie* suggests sculptured medallions of the heads of the fathers of photography as being more decorative and more easily understood than representations of the houses in which those *savants* resided. We endorse the advice. At the same time, if the collection is to be complete, we should like to see places found for a few more "fathers" of English birth besides Talbot, such, for example, as Herschel, Scott Archer, Ponton, and others.

Ladies at Photographic Societies.—In America, as we have from time to time reminded our readers, there are one or two camera clubs and photographic societies which receive a large share of active support from the members of the fair sex. In this country, on the other hand, ladies take little or no part in society life, excluding, of course, lantern nights and suchlike gatherings, which do not count. Things are about the same, from all we can gather, on the Continent. We extract the following line from the proceedings of a recent meeting of the Société Génevoise de Photographie: "The ladies, who had been specially invited to this meeting, were conspicuous by their absence." Perhaps it was wet, perhaps there were counter attractions; perhaps, again, the ladies knew what was on the agenda, "saw the snare, and then retired." Analogies between the eye and the camera: orthochromatic plates and hand cameras, are not a safe draw for the ladies, gentlemen of the Société Génevoise de Photographie.

A Cry of Alarm.—*La Tribune Photographique* publishes an article under this heading in which it makes an endeavour to rescue the stand camera from the cold shade of neglect among amateurs, into which the rage for hand cameras is undoubtedly driving it. "There are," it says, "certain kinds of objects to which we refuse to assign the name of apparatus, and that are brought before raw amateurs as supplying, for a few francs, the very latest advances in cabinet work, optics, and, of course, cheapness." It is against this kind of thing (*i.e.*, the hand camera) that our contemporary utters its "cry," expressing its preference, nay, even its tender regard, for the good ordinary camera, mounted on its tripod, with its double slides, its battery of lenses, its focussing cloth, &c. It is a little heavy, says the *Tribune*, pleadingly, a little cumbersome, nay, it is sometimes troublesome on an outing, but it has its (the *Tribune's*) preference for, all that, and why? Because—well, because, in brief, the ordinary camera allows of results being obtained which are denied to the hand camera. Has the *Tribune*, to quote Mr. Cimabue Brown jun., "been subsidised to write down hand cameras?"

Panoramic Lantern Slides.—In March last, at the Conservatoire des Arts et Métiers, Commandant Moessard lectured on panoramic photography, and showed his audience the effects of panoramic perspective on the screen. The latter was semi-cylindrical, eight metres wide and two and a half metres high, the linen being stretched on a frame having the shape of a part of a cylinder of six metres radius. At a point corresponding with the centre of an imaginary circle, of which the screen formed a part, were placed four lanterns, each projecting a portion of a panorama. The most difficult part of the operation was to join the four views exactly, so as to make a continuous panorama; but this was overcome by each view showing at its edges a part of the next view to a width of two or three millimetres, the views being marked so as to make them coincide at the proper places, the illumination of the junctions being levelled up to that of the remainder of the picture by screens in front and at the sides of the lime.

Orthochromatic Plates for Stellar Work.—In the *Annuaire* for 1892 (a French astronomical publication) there is a note, signed by Messrs. Paul and Prosper Henry and Messrs. Plummer and Scheiner, stating that the commission which has examined certain stellar photographs on isochromatic plates finds that such plates are unsuitable for obtaining negatives for the chart of the heavens, the stellar discs being surrounded by a strong aureole, due to the chromatic aberration of the red rays caused by the lens. With the smaller stars this aureole is less intense, but with stars of mean magnitude it is quite dark, and thus increases the diameter of the stars. It is therefore impossible, the note proceeds, to estimate the stellar magnitude on these plates. To this note M. Léon Vidal appends some observations expressive of the difficulty of accepting the conclusions come to. He points out that there is no *à priori* reason why orthochromatic plates should be rejected for the work of mapping the heavens, and also says he thinks them the only plates suitable. Competent specialists should have been consulted by the Committee. But we should like to ask the Messrs. Henry whether non-orthochromatised plates would be insensible to "aureoles produced by the chromatic aberration of a lens?"

COLLODION EMULSION NOTES.

THERE are one or two points in connexion with Mr. Alexander Mackie's paper on *Collodion Emulsion* before the London and Provincial Photographic Association on which I should like to say a word. First, with regard to the use of bromide of ammonium, I quite agree with Mr. Mackie in preferring that salt to any other where circumstances admit of its use, although, as he says, I have recommended the double salt of cadmium and ammonium. As far back as 1865, and for some years later, ammonium was my sole bromide; but, as the emulsion process became modernised, and special makes of pyroxyline were introduced, it ceased to answer as perfectly as heretofore. With a good-bodied and somewhat horny cotton, made at a moderately low temperature, it is all that could be desired; but when it comes to "high-temperature" and other "fancy" samples, it requires to be tried first, and it may or may not answer.

Another reason for giving it up, or, rather, for recommending the double salt, was the far greater solubility of the latter. Without using water, it is only possible to get something like five grains to

the ounce of ammonium bromide into solution, and here again, with many of the modern cottons, this is not sufficient. The use of water is not altogether objectionable, but it is to be avoided as much as possible, for what with that contained in the solvents, and used in dissolving the silver and bromide, the emulsion becomes pretty well loaded at the finish. This is not a matter of so much importance in the case of a washed emulsion, or one that is to be washed, because in drying the excess is got rid of, and the pellicle can be redissolved in strong solventa. But, in the case of an unwashed emulsion, every drop of water is of importance as adding to, or causing, crapiness, mottling, and a host of troubles. Its presence, too, in a great quantity has a detrimental effect on the fineness of the suspended bromide.

Turning to Mr. Haddon's suggestion *re* precipitation, that is no doubt the ideal method of washing out the soluble salts, if only it could be relied upon. That, however, after a very long experience, I am compelled to say is not the case. Very few samples of pyroxyline will bear precipitation at all without losing all the vigour that the unwashed emulsion possessed, and some even separate from the bromide. Even those that are amenable to precipitation are not to be relied upon invariably, as without any apparent reason they will fail to precipitate satisfactorily. I have tried large and small proportions of water, hot and cold, pouring the emulsion into the water and the water into the emulsion, in fact, have rung the changes pretty effectually in my endeavours to arrive at a reliable precipitation method, but I have to confess I have not succeeded.

Curiously enough, at first sight, the form of pyroxyline that stands precipitation best is that which has been already once dissolved and precipitated, as in the process published by Chardon, to which allusion was made at the meeting. In this process, which, as old collodion emulsion workers will remember, took the prize offered by the French Photographic Society for the best dry process some fifteen years ago, M. Charden made use of two kinds of precipitated cotton, which he named "*coton résistant*" and "*coton pulvérulent*," and which were thrown down from their solution in ether and alcohol by cold and hot water respectively. The two products were supposed to possess different properties, but beyond a slight difference in appearance and of solubility—the latter of the two being bulkier and more soluble than the other—I could never detect any great distinction between them, nor, with the exception I have named—they stood re-precipitation better—any advantage over ordinary cotton.

The most remarkable features about this precipitated cotton are its great solubility, and the fact that it frequently weighs as much as, or more than, the original cotton dissolved, in spite of unavoidable losses both in dissolving and precipitating. With regard to the solubility, I have known a sample of pyroxyline, that gave a scarcely usable collodion with eight or ten grains to the ounce of solvents, to show a solubility after precipitation to the extent of seventy or eighty grains, and still give a perfectly fluid and fluent collodion. In fact, there seemed to be practically no limit to its solubility. The increase in weight was, no doubt, attributable to a change of condition of the cotton by precipitation, a change somewhat of the nature of, if not exactly so, a direct hydration of the nitro-cellulose, a reaction that wae stated to take place, by one of the earlier French experimentalista—Blondeau, I think—by the precipitation of dissolved gun-cotton.

Other experimentalists in the action of water upon collodion and pyroxyline, including Hardwich, have shown that a portion of the cotton remains soluble in water, and therefore there should be a decided loss of weight in precipitation. Whether any portion is soluble in water alone I am unable to say from personal experience, but that a very considerable quantity of matter is removed by precipitation may be easily demonstrated. If a quantity of collodion or of emulsion be poured in a fine stream into a moderate volume of water, and well stirred until the flocculent and pulverulent portions of the precipitate have separated, and the clear liquid be then poured off and set aside for a while, it will be found, in the course of an hour or two, to have become semi-solid or gelatinous, or a thin jelly will have separated from the rest of the liquid, according to the volume of water used and other circumstances. From the interval that elapses between precipitation and the gelatinising of the liquid, it seems to me clear that it is the *diluted solvents* that retain a portion of the pyroxyline in solution, and that, as the more volatile portions of the residual liquor evaporate, the solid matter gelatinises, owing to its insolubility in water alone or very dilute alcohol.

I mention these changes and phenomena in order to explain the utter unreliability of the method of washing emulsions by precipitation. When such important changes take place as the chemical absorption of water and the elimination of a considerable portion of the original pyroxyline, the latter is necessarily converted into an entirely different substance from that which is obtained by driving off the solventa by evaporation before treating the residue with water. If I add to this the no less important matter of the possible removal, along with the soluble portion of the pyroxyline, of valuable organic constituents of the emulsion, I think no more need be said against the adoption of precipitation, no matter how *convenient* the method may seem.

As a matter of fact, scarcely any two emulsions behave in identically the same manner, even when precipitated under precisely the same conditions as far as can be secured. One will sink to the bottom in heavy clots, another will float to the surface in large flocculent tufts, or will aggregate into a frothy or pasty scum which, after a while, solidifies into a solid cake; and, lastly, it is a very common occurrence to have the precipitate—or rather, product—divided into two distinct portions—one a flocculent, "cottony" mass that floats, the other a heavy, sandy deposit that settles to the bottom, and which dries into a soft, coarse powder. In this instance it would seem as if the emulsion had divided itself into two distinct portions, one of which contained a surplus proportion of cotton, the other an excess of silver bromide, and that their characters would be entirely different. But I have dissolved the respective products in such cases separately, and compared them, without being able to detect the slightest difference, either physically or photographically, and whatever qualities were possessed by either—usually inferior—the other shared them equally. *(To be continued.)* W. B. Bolton.

WHY PHOTOGRAPHS FADE.

IV.

We now come to the subject which is still to most photographers and to professional ones most certainly, of the greatest importance, that of the deterioration of their albumenised silver prints. Any one who has gone into this matter will agree with me that, whichever way one turns, one meets with most strange results, that seem to baffle all explanation, or, at least, appear to be governed by no fixed law. One finds, perhaps, that some waste print, which has been little more than rinsed after coming out of the hypo bath, stands tests that bring a print on which every care had been expended to grief. On going into this subject I soon found that the only way would be to go right from the beginning, inquire into every stage of the preparation of the paper, and every detail of manipulation, &c., during the production of the prints, and then endeavour to find out where the mysterious, though, as we know by results, most important, details of manipulation are which cause the fading of our prints. One may use the one sample of paper, tone and fix in the same strength baths, for the same length of time, wash the prints under similar conditions, as far as we know, and yet some, after twenty years, will be found, practically speaking, unchanged; others, after a year or two, will be found to begin to be going all wrong.

During my experiments I have most certainly come across many things which appear to explain nearly all of the causes of the deterioration of our prints; and if, by stating the various points I have found out, I can give a clue to the other workers, or, what would be even better, if we could get some Photographic Society, whose members have more time, and have better opportunities to conduct an exhaustive inquiry into a subject of this kind than I have, I shall feel very pleased, because I am quite certain of one thing, and that is, that the photographic printing process of the future must be a printing-out one—that the lightest tints in the picture must be seen, so as to get just the depth of tint required, and that the weak points in a negative may be dodged with certainty.

Platemakers and others may advertise and talk nonsense for ever about isochromatic or other wonderful plates, and the operators may be as skilful as possible, but as long as a lens will take everything in a landscape that is before it, with the uncontrollable amount of light and shade, success will depend upon the skill and artistic taste of the man who produces the print. I do not believe that there is one

in a hundred landscape negatives that the best possible result can be got from, without a certain amount of so-called dodging on the part of the printer; and, to be able to do this, and prevent a most serious waste, he must be able to see what he is doing.

If amateurs would only take one-half the care in printing that they do in the production of their negatives, they would find their average work very different. The only things many seem to trouble about are the make of the plate, and the formulæ for development.

But to return to the question of fading. If we carefully examine a collection of good old albumen prints, we shall find that there has been a yellowing of the white parts of the prints, and possibly a slight reduction of the density of the image; to an extent, the latter will be more apparent than real, due to the loss of brightness in the high lights, so that the initial cause of the deterioration of the prints will be found to be due to the sickly yellow look of the parts which should be white. This must be due to one of three primary causes. Either the paper itself yellows from exposure to minute traces of sulphuretted hydrogen in the atmosphere, or the fixing bath of hyposulphite of soda does not dissolve a compound of albumen and silver in the film, which compound is changed into the yellow form of sulphide of silver in time by the action of the sulphuretted hydrogen, or the hyposulphite of silver dissolved in the excess of hyposulphite of soda is not entirely washed out of the film, this hyposulphite of silver being in time converted into sulphide of silver.

We will go into these causes separately. In all my tests I have never been able to trace the yellowing to the paper itself. I once tried coating papers with albumen, gelatine, arrowroot, &c., without any silver, but I soon found that it would give me no ground to go upon, because with the vehicles used would have to be first formed the organic silver compounds that are formed in our printing papers before they could be exposed to any conclusive tests. Besides, there is no doubt that the faded, yellow look of an old albumen print is due to the presence of minute traces of silver left in the film, and afterwards converted into a sulphide of that metal by the atmosphere.

We have to find out, then, what causes the silver to be left in the film, and what are the contributory details of manipulation which produce the deterioration of prints more rapidly in some cases than in others. It is of no use to say that a print has not been properly fixed, or that the hypo has not been perfectly washed out. What one wants to know is the reason *why* these manipulations are not carried out as perfectly at one time as at another.

With the old plain, salted paper prints, properly fixed and washed, the silver seemed to be easily and entirely removed from the high lights of the pictures, but with albumen prints I have never found any which would not, when tested, show more or less the presence of yellow sulphide of silver in the light parts. Some one may say that is easily explained—viz., because silver does not form a definite compound with gelatine as it does with albumen; but I have proved that this is not by far the only explanation. There is no doubt that in fixing a print a great deal depends upon the physical condition of the vehicle used. We see exactly the same thing in other photographic work. For instance, I can make two silver bromide emulsions, containing exactly the same quantities of silver and gelatine on each plate, and yet, on development, one can be developed so dense as to be useless for practical purposes; with the other, do what one will, it would only show the ghost of an image.

We get similar results in toning. The old plain, salted papers could be toned with an old toning bath, after the gold had been almost all used up by toning albumen prints first, and yet many of the modern chloride emulsion papers can only be toned by a very strong sulphocyanide toning bath; in the former case the reduced chloride of silver is on the gelatine (so to speak), in the latter it is in the film.

Old wet-plate workers will know what I mean by the physical conditions of a film controlling the results by reference to the sensitising of a collodion plate. The glass coated with collodion, and put into the silver bath as soon as it had set, would give a good creamy film of iodide and bromide of silver. But if the ether and alcohol were allowed to evaporate, and the film to dry before putting it into the silver bath, we would not obtain the same perfect formation of the silver haloids, because the hardening of the collodion had bound up the bromide and iodide of cadmium, &c., in the film, and the affinity of the silver for those salts would not be strong enough to destroy the physical protecting power that the collodion has over the soluble haloids in the film.

HERBERT S. STARNES.

COLOUR IN THE CAMERA.

[*Philadelphia Record.*]

THE first public lecture illustrated with specimens of coloured photography was recently given at Association Hall, under the auspices of the Photographic Society of Philadelphia. Scientific demonstrations of the Ives process have been previously made at the Franklin Institute, but these were purely of a scientific nature. The hall was filled to the roof by an enthusiastic audience, and every view in colours was received with applause that brought blushes of pride to the cheeks of F. E. Ives, the pioneer of coloured photography, who worked the stereoptican end of the lecture from the balcony.

"From Philadelphia to the Grand Canon of the Yellowstone National Park" was the subject chosen for the lecture. Mr. Ives furnished the coloured photographs, while Mr. W. N. Jennings furnished the plain photographs and delivered the lecture. In his introductory remarks, the latter paid a graceful tribute to his co-labourer. "When, about thirteen years ago," he said, "Mr. Ives undertook to reproduce, by means of photography, the colours of nature, he fully realised that no light task was before him. Year after year he kept steadily at work, determined to win the battle, till at last success crowned his efforts."

The first few views were from plain photographs, but when the first coloured photograph was projected the audience gazed spellbound. For a moment there was a dead silence. Then, as one man, the large audience burst into applause that lasted for several minutes. From that moment the success of the lecture was assured.

NO BRUSH EQUAL TO THE MAGIC LENS.

When thrown upon the canvas, the coloured photograph is a perfect miniature of nature. No oil painting could possibly produce even an approach to the effect caught in the magic lens of the colour camera. The delicate cloud effects, the various tints of foliage and water, the different colours in the rocks, all are perfect. The view of McCartney's cabin, the first hotel established in the Park, is a thorough test. The many gradations of colour in the landscape are brought out perfectly. Where the logs of the cabin have been exposed to the weather, they have become bleached, while those in the shelter of the overhanging eaves still retain their natural orange-brown colour. The grass in the foreground suffers from a lack of moisture; while that in the rear of the cabin, fed by a mountain stream, is a bright, fresh green. Another shade of green is visible in the window blinds, and still another in the dark pines on the hillside. The dark indigo blue of the sky stands out in bold relief. All the colours of the original landscape, and its finest gradation of light and shade, are here most faithfully reproduced.

Mr. Jennings' lecture was delivered throughout in a delightfully chatty vein, interspersed with wit and anecdotes of no mean quality. His own plain photographs—many of which were character sketches—added much to the charm of the entertainment; but, as he himself admitted, the crowning feature was the perfection of Mr. Ives' experiments with the colour camera. The Yellowstone Park was chosen because of its variety of colour. The scene from Jupiter's Terrace is full of it. In the foreground is a small pool. In the centre, the water is almost boiling, from which radiate delicate bluish-green silken threads, gradually running through the scale of colour, until at the edge of the pool it assumes a deep purple. The cliffs of Golden Gate afford an excellent opportunity for the reproduction of colour in rocks.

"Even the most prominent impressionist," said the lecturer, "wrings his hands in despair as he gazes upon this marvellous mosaic, and frankly confesses that brush and pigment in the hands of the most skilled artisan fall far short of doing justice to this masterpiece of nature."

MR. IVES' PROCESS.

Mr. Ives has patented his process, which he thus describes technically: "By means of a very ingenious compound camera front, three photographic negatives of the object are made by simultaneous and equal exposure, from the same point of view, and upon the same sensitive plate. The photographic plate is sensitive to all colours of light, but, by introducing light filters, one of the negatives is made by such light rays only as excite the fundamental red sensation, and in due proportion; another by light rays as they excite the fundamental green sensation, and another by light rays as they excite the fundamental blue-violet sensation.

"From this triple negative a triple lantern slide is made, which, although it shows no colour, contains such a graphic record of the natural colours that, in order to reproduce them to the eye, it is sufficient to superpose the three images, one with red light, one with green, and one with blue-violet. This is accomplished either in Mr. Ives' new heliochromoscope, a device about the size of a hand stereoscope, and used in much the same way, or by projection with a special optical lantern having three optical systems, with red, green, and blue glasses.

"The process is as scientifically accurate for reproduction in colour as ordinary photography is for reproductions in monochrome, but at present can be carried out successfully only by a scientific expert, employing the spectrograph for testing the sensitive plates, and adjusting the selective colour screens. When such preliminary adjustments have been correctly made, the process is almost as simple and reliable as the ordinary negative process. By a modification of the process, introducing further complication, colour prints are made on glass or paper, but the comparative simplicity of the plan of superposing images commends it to scientists, and is more convincing to the general public."

THE CAMERA AND THE CONVENTION; OR, PICTURESQUE SCOTLAND AND PHOTOGRAPHY.

I.

Since the Convention of the United Kingdom is to be held in "Bonnie Scotland" this year, we think there could not be a more fitting opportunity for giving a few outline sketches of "where to go with the camera" in and around the vicinity of Edinburgh, the place of meeting, and to point out some spots which, being of special historical interest, possess at the same time pictorial interest, a combination that is not always to be met with.

The month in which the Convention meeting is held, viz., July, is propitious for a holiday, and many of our readers may be induced to stay a much longer time than the *Conventional* week in the land of the mountain and the flood, so that an extended field of observation, which we mean to make, may be of interest to them.

Necessarily, a good deal of hurry is needed to overtake the days' outings at the Convention trip gatherings from a not unnatural desire to go over as much ground and take as many pictures as possible in the time, but we have found this in some cases to be a considerable disadvantage. Take, for example, one of the Bath Convention outings, "Glastonbury and Wells;" certainly either of the places was sufficient to supply ample material for quite a wealth of pictures for one *day*, and, in our opinion, hurrying to both to some extent spoiled both.

To avoid this, a general knowledge of the varied places of interest, obtained beforehand, must be of benefit to those anticipating the pleasure of going to the meeting, and, when too much is crowded into one day to suit their convenience or taste, the part that commends itself can be chosen, and the hurry obviated.

The following outlines are given quite outside of any knowledge of the places chosen or trips contemplated by the Convention Executive, a list of which has not been yet issued when we write this; but we are sure that most, if not all, the points will be embraced in our notes upon the subject.

Edinburgh.

The place chosen for the Convention meeting of this year is a most charming one, both historically and pictorially. Edinburgh stands out as a city of cities from its many natural advantages, which lend to it panoramic effects and beauties not to be surpassed anywhere, and from an historical standpoint it teems with interest. Looking at it from a *cameramic* point of view, it would take far longer than the week to do it anything like justice. The various points of view—and interesting bits to photograph from the Princes-street Gardens alone—would, if produced, themselves fill a book, in the midst of which the Castle—ever imposing—towers above all, guarding the city.

With regard to the Castle there is a good story told about a poor tailor who had "whipped the cat" from Edinburgh as far as London, and, after many vicissitudes, returned home by boat to Leith, and walking up from Leith, turning the corner of Leith-street at the Register House, the Castle, towering away in the west, burst upon his view, and the poor man dropped upon his knees, exclaiming, as the tears ran down his cheeks, "Oh, my bonnie Castle! oh, my bonnie Castle! I hae never seen such a winsome sicht since I left ye." And we fancy a feeling akin to this must come to many people when the first glimpse of this scene meets their view on a return visit to the city, no matter how often they have been there. We must confess to experiencing a thrill of pleasure akin to the old tailor's every time we visit Edinburgh; the panorama spreading itself out before us as we walk up from the Waverley station is ever charming and ever new.

Views from Calton Hill.

A general view of the city is best obtained from the Calton Hill, but it is only at certain times that this can be got. The professional photographer has sometimes to wait day and days to get a clear picture of this view, the haze and smoke in the sunny distance preventing the further west parts, such as the Castle, from being successfully rendered.

Should the wind chance to be in the right quarter, however, and the distance clear, this subject makes a beautiful panoramic picture, embracing Princes-street, Scott's Monument, National Galleries, and the Castle in the distance, producing a truthful rendering of one of the impressions of the place that lives with us always.

The gaol, which stands immediately under the Calton Hill on the south—which, by the way, looks more like a castle than a gaol—makes a good picture from the railway or North Bridge side, bringing in the Calton Hill and its monuments as a background.

On the Calton Hill itself there are some bits of interest, such as the National Monument, which stands a ruin, and more picturesque, probably, in this state than if it had been completed. The original intention was to produce a building like the Parthenon, in memory of the heroes of Waterloo; but subscriptions failed, and so it stands unfinished. There is Dugald Stewart's and other monuments, but the Calton Hill boasts more of interesting things, rather than any that could be termed pictorial, unless you turn to the view that you get from its height. North, stretching away across the Forth to Fife; west, away beyond the Corstorphine Hills; east, as far as the Isle of Man; and south, where stands Arthur Seat, with all the country beyond; with the High School and Burns' monument lying in the near distance, under the shadow of the hill.

This circular panorama will well repay a visit, although, from a photographic point of view, the general effects are too mappy, and there is nothing of sufficient prominence in the foreground to help out a picture.

The Old Town.

Leaving the Calton Hill, and coming along Waterloo-place to Princes-street, the part of the general view that attracts us most is the back of the buildings of the old town west of the North Bridge, towering up ten or twelve stories high, on the other side of the valley, in which the railway and East Princes Gardens lie.

This has always been a favourite picture of old Edinburgh to and from East Princes Gardens. From the hotel windows in Princes-street the best positions for picture-making will be found.

Here you have also Sir Walter Scott's monument, which well repays a few plates.

Between the Gardens east and west is the Mound, on which site stands the Antiquarian Museum and National Gallery of Painting. These compose well for a picture with the Castle in the background. The Castle itself can be had from many points, both in the east and west gardens; also another picture of the Castle can be had from the Grass Market side, down by the King's Stables; this view shows its great height, hence more interesting than pictorial. Along the whole line of Princes-street the choice of subject is very varied, and the ease with which good positions can be obtained for getting in the desired subject and effect is light work compared with most cities we have visited—all round, it is so free and open.

Holyrood Palace.

The older and more historical part of Edinburgh naturally begins at Holyrood Palace.

Year by year the old landmarks are being obliterated, and places of historical interest are being pulled down, and carted away to oblivion, leaving nothing but the ground on which they stood to mark the places where history was made.

As an instance of how these relics of the past gradually disappear and are forgotten, we once went to photograph an old archway down the Canongate. This archway formed the entrance to the house where Darnley slept the night before his marriage with Mary Queen of Scots. When we reached the spot, the archway was all gone, and in its place were erected two square sandstone pillars. We went into the building, and there, on the ground (for the house now there is more modern) where Royalty used to revel, we found workmen toiling for their daily bread.

The Palace of Holyrood, however, still stands in all its sombre grandeur, and, this being a centre of great historical interest, pictures of the chapel and its surroundings will be desired by all.

The Chapel Royal, a ruin within the palace grounds, should be photographed, and there is an old building to the left of the palace, and nearer Abbey Hill, named Queen Mary's Bath-room, which makes a good study.

The Canongate.

Coming up the Canongate from Holyrood, about half way up on the right-hand side, is the Canongate Tolbooth, a good specimen of the French style of architecture, and in the Canongate churchyard (which is a little lower down) Ferguson's tombstone, erected by Burns, will be found; Adam Smith, the author of the *Wealth of Nations*, is also interred here. All the way up the Canongate and High-street, every here and there will be found quaint old blocks of buildings, with half-obliterated coats of arms and inscriptions, set in the doorways or on the fronts of the houses. New streets and city improvements are fast sweeping away many of these relics that delight the hearts of the antiquary and enthusiast; but there are still a few left for the photographer who takes delight in such subjects. John Knox's house on the same side of street, and St. Giles' Church higher up on the other side, are both good subjects for the camera. The buildings that form the square round St. Giles are the Parliament House, now used as the Supreme Courts, and the Advocates' Library, &c.

At the top of the Castle Hill, in a lane to the right, will be found Allan Ramsay's house (the author of *The Gentle Shepherd*). Then we

come to the Castle Esplanade and Castle interior. The view from the Castle is very charming, but, as can be well understood, photographs of the Castle, houses, squares, and rooms, are valuable principally for their historical interest.

Old Buildings and Monuments.

In the closes which run from the High-street to the Cowgate many remnants of old buildings remain, full of history and interest, which would well repay a prowl round for three or four hours.

To those who take an interest in monuments, memorials, and old gravestones, they will find quite a wealth of subject in the old Greyfriars Churchyard.

The buildings in Edinburgh of a public nature, such as banks, hospitals, and other institutions, are very numerous and very handsome, and will doubtless commend themselves to the exposure of many plates.

Arthur's Seat of itself does not make much of a picture, but St. Anthony's Chapel over St. Margaret's Loch is a pretty little bit, and beyond the Arthur-street entrance to the park is the Laird of Dumbiedyke's house.

Some spots of interest specially connected with Sir Walter Scott's *Heart of Midlothian* are situated in the Queen's Park, such as the site of Jeanie Deans' house, and the cairn where Jeanie Deans met Robertson is still shown close to the Peirshill Barrack entrance, but from a photographic point of view it is useless.

RATIO OF GRADATION.

Our letter in reply to Mr. Channon, which you were good enough to publish in your issue of April 22, was not altogether superfluous after all, since, in his last article, Mr. Channon makes no further reference to any of the previous questions of the controversy; there is no mention of Plener's formula nor of the "law of error." Mr. Channon has all at once plunged into a new question as to which of the two formulæ proposed by ourselves most accurately represents the action of light upon the sensitive film.

Our approximate formula appeals to Mr. Channon's sympathies for the same reason as did Plener's formula, namely, that he is able to support it by what appears to be clear mathematical reasoning, which, however, again involves assumptions as to the properties of plates and of the light, which are directly opposed to experimental facts.

Whatever fault may, in the future, be found with our research, there is one fact which we have established with great certainty, namely, that there is not now a photographic plate in the market to which the formula advocated by Mr. Channon applies in any other sense than as a rough approximation. We are equally certain that there is not at present a plate to be found for which the formula we have termed the "correct formula" does not fairly represent the variations in the density after development due to changes in the exposure. The last paragraph of our original paper shows how far we ourselves understood this formula as final.

In the absence of any experimental proof on Mr. Channon's part that the straight line represented by our approximate formula more aptly delineates the action of the light upon the sensitive plate than the curve with point of inflexion, of which the "correct formula" is the equation, we do not feel it necessary to minutely criticise Mr. Channon's reasoning, which leads to anything but a truthful rendering of the facts.

It may, however, be well to correct a few misunderstandings of our meaning which have inadvertently crept into Mr. Channon's article.

Mr. Channon states that we considered the whole of the light absorbed by silver bromide as effective, or that, at any rate, we had made no reference to any possible change into heat. If he will again examine our definition of the symbols used, he will find that this statement is a mistake.

Mr. Channon's second misunderstanding is with regard to the symbol dx used by us. To him, as a photographer, with the microscopic picture of the developed plate in his mind, the symbol is indefinite, because he seems to associate it with the finite particle he sees. To Mr. Channon, as a mathematician, the symbol is, we feel certain, perfectly defined by what is implied in the whole treatment of the subject—namely, $\int_0^a dx = a$. We should say that the particles represented by dx are magnitudes of the order of molecules, and have nothing whatever to do with Mr. Channon's visible particles. If he will carefully consider the length of time dt, the difficulties of the subject due to the indefiniteness of the symbols will vanish.

Mr. Channon, from his unproved point of view that no light capable of affecting the plate will escape at the back, finds it difficult to see what the loss of light at the back has to do with the densities produced on the plate. If he were to spend in the laboratory a portion of the time which he devotes to the writing-table, and to supplement his reasoning with an experiment on the lines of the following, made by ourselves, he would derive considerable assistance.

1. Behind a slow plate another plate of the same kind was placed, and several different exposures were given. Both plates were developed together, and the resulting densities were found to be as follows:—

Front plate	·535	·785	1·035	1·286
Back plate	·030	·100	·230	·370

2. In front of an Ilford extra rapid plate a strip of a slow plate was placed, and also a strip of opal glass of apparently the same opacity as the slow plate. A third portion of the Ilford plate was left uncovered. Four different exposures were given of 15, 30, 60, and 120 seconds, respectively. The densities which resulted after development were as follows:—

Densities on Ilford.	15″	30″	60″	120″
Exposed directly to light ...	1·520	1·700	1·90	2·14
Behind opal glass	1·11	1·39	1·62	1·88
Behind slow plate	0·92	1·26	1·57	1·82
Densities on slow plate ...	0·93	1·46	1·89	2·20

These experiments clearly demonstrate that the energy at the back of the plate is not a negligible quantity, and that it acts behind a sensitive plate in the same manner as behind an opal glass in which no chemical change takes place.

Quantitative experiments like these constitute whatever real value our research may possess. The theories and opinions therein are valuable only in so far as they suggest new experiments and help to connect isolated facts, or to apply in practice the results of the experiments. It is the production of more of these quantitative experimental facts which at present occupies such time as we have at our disposal.

BROMIDE ENLARGING.

[Newcastle-on-Tyne and Northern Counties Photographic Association.]

I need hardly dwell upon the advantages of enlarging, so as to be able to make large prints from small negatives. Few words are necessary to convince any one of the value of being able to make pictures suitable for hanging from negatives which can be taken in a very small camera, whilst the taking of such direct from large negatives requires a camera which many of us cannot afford, besides which the extra labour in carrying a 15 × 12 camera and slides about the country necessitates an amount of work which not only many of us would not care to undertake, but which in many cases is almost impossible. Besides, amateurs, at any rate, don't want large prints by the score, but, as a rule, like to have a few prints from their best negatives of such a size that they can be seen without a magnifying-glass, and it is to them that my remarks will be specially directed.

A great deal has been said about enlargements as compared with direct prints; but although I do not approve of "fuzzy" prints of any kind, I decidedly prefer a good enlargement of any size above 12 × 10 to a contact print of the same size, and from a negative taken direct in the camera.

A good enlargement of, say, three or four diameters, which need not be overstrained, has a softness in it which gives it a charm not possessed by a direct print of the same size.

Very fine definition is not required in pictures of 15 × 12 or over, as in the small sizes, because when we look at a 15 × 12 picture we usually stand a few feet away so as to see the whole picture, whilst in looking at smaller pictures we view them much nearer, and finer definition is then desired.

As it would be impossible for me to-night to go through and describe all the processes of enlarging which most of you already know, I will confine myself to giving you some of the results of my own experience, hoping it may prove of use to any who wish to try this branch of photography for themselves.

The Negative.

With regard to the negatives, I usually take quarter plates, as I find that they can easily be enlarged to 15 × 12, which is almost four diameters, without in any way overstraining, so as to cause "fuzziness," and, as that is generally large enough for most amateurs, I think quarter-plate negatives have many advantages.

Of course, half-plates or whole-plates can be as easily enlarged as

quarter-plates when daylight is used, but when artificial light is used and a condenser is necessary, then quarter plates are more easily dealt with, as the expense of condensers for larger sizes is a serious item.

After all, a half, or even a whole-plate, is a small picture, and is more suitable for an album, and if we take negatives for the purpose of enlarging, we might just as well enlarge a quarter-plate as a half-plate. There is a slight objection to the use of quarter-plates, and that is when we enlarge them up to, say, 15×12 from a negative taken with an ordinary focus lens, the perspective is rendered incorrect; for instance distant objects appear nearer than what they are in nature; but in picture-making this is, as often as not, an improvement, whilst, when they are not so much enlarged as, for instance, to 10×8, which is about two diameters, they are more correct than the original. As bromide enlargements are the most commonly produced, and are in most respects the easiest, I will confine my remarks to this class.

The simplest method is, of course, to expose from the negative direct upon the bromide paper, and when this is properly done, the results are hard to beat. There are other ways, namely, to make a transparency of the size of the negative by contact, and from this make an enlarged negative. Or make an enlarged transparency, and from this make a large negative by contact, and from this print your enlargement. These latter processes are well adapted, when a large number of prints are required, as, of course, each enlargement can be printed in the printing frame, and much time saved, but if only two or three are required, there is no need to go to this extra trouble of preparing an enlarged negative, as the first process will yield results which cannot be surpassed, and it has the advantage of being simple, whilst the more processes you introduce the more difficult it is to succeed.

Negatives for enlarging should be full of detail, and not too dense and sharp to the edges. I usually take them with stop *f*-32 and develop them without much bromide in the developer, just sufficient to keep them from fogging, as they should be quite clear.

Any amount of contrast can be had in the enlargement by using sufficient bromide when developing it. It is astonishing what excellent enlargements, with plenty of contrast, can be made from negatives without much contrast, whilst negatives with great contrast are unsuitable for enlarging. The only way to treat these is to subject them to a very powerful light, as a weak light, acting for a longer time, has not the same effect. The image being on the surface of the paper, the deep shadows get blocked up before the other parts are brought out, and show no detail in the denser parts, which is not the case in a negative or lantern slide, which is viewed by transmitted light, when the detail in the denser parts is easily seen.

Another advantage in using a small stop when taking negatives for enlarging is that you get more even negatives, so that the density at the centre is not greater than that at the edges, whereas with a large stop more light strikes the centre of the plate than the edges, and consequently the density is greatest in the centre. Negatives suitable for enlarging make excellent direct bromide prints, if developed in the same way.

The Apparatus Necessary.

Either daylight or artificial light can be used. When daylight is used various means can be adopted, but I think the best and simplest way is to place the negative towards a window, and photograph it, so that to do this you must have a light-tight box of the size of the enlargement, or, in other words, a substitute for a large camera. This does not require the room to be darkened, nor to have to work in a dark room, and is, I think, a simpler method than having to block up a window, which is not always an easy thing to do, the camera taking the place of a dark room. This is best made with a large bellows, to one end of which is fixed the front for carrying the lens, and to the other end a frame is fixed, to which a dark slide can be fitted. A hinged door could be used, on which the bromide paper is pinned, but a dark slide is much to be preferred, as the paper can be shut up and carried to the dark room to be developed, whereas, if the paper is only pinned on a board, it would have to be developed in the same room, or the whole apparatus carried bodily away to avoid the light.

This apparatus can be bought very cheap already made of any size up to 15×12, and is, I think, very convenient.

A rigid box can be used instead, when the lens is inserted at one end and the other end left open, in which case an easel is made to slide in at the back for focussing, and on which the bromide paper is pinned, and a piece of cloth hung over the back of the box to exclude any extraneous light. In each case a piece of ground glass is substituted when focussing, and in the case of the rigid box a mark must be made, so that the easel can be placed in the same position. But a camera with bellows has many advantages, as it is more easily worked for focussing and can readily be made, and a dark slide for holding the paper could be bought and fitted to it. The dark slide can be had fitted with carriers for holding any size of paper, in which the paper will easily stand upright when supported at the corners, like a plate, especially if the thick paper be used; if not, it can be held between two pieces of plain glass without harm.

The best way to fix the negative for illuminating it is to fix it in the camera in which it was taken, either by having a holder to fit in the position of the ground glass, or place it in a dark slide and open both slides; then place the camera with the negative towards the light and the lens-hole pointing inwards, the lens having been removed and inserted in the larger camera.

The lens used in taking the negative answers admirably; but if a short exposure is preferred, then a portrait lens can be used.

It is better to have a long board to hold the two cameras, so that the larger one, containing the bromide paper, is at one end, and the smaller one, containing the negative, upon a small table at the other end, so that the lens-hole of the small camera will be on a level with the lens in the large camera, each of these sliding between beads at either side, so as to keep them parallel. This saves a lot of time in centering, as when once they are set, then at whatever distance they may be removed for focussing they are always centred.

The board, with the whole arrangement, can then be rested on the window sill; and a good slope should be given, as this is very desirable, and if used with artificial light, is simply placed upon a table.

The Illuminant.

When a dark room can be used, then the window is first blocked up, leaving an aperture of the size of the negative to be enlarged. The ordinary camera or an enlarging camera containing the negative is fixed up against the aperture, with the lens pointing inwards, so that no light can enter the room except that which comes through the negative. Of course, the ground glass is removed and the negative inserted in its place, and an easel for holding the bromide paper placed at the required distance from the lens. The camera must, in this instance, be able to extend to twice the distance of the focus of the lens used.

A window facing the north is to be preferred, or wait until the sun's rays do not fall direct upon the negative, as direct sunshine is not desirable. It is also better to be as high a possible, and to have an open view, so as to avoid houses opposite, as chimneys, &c., obstruct the light and often cast a shadow over the negative, which will show in the enlargement. In this case a mirror or sheet of cardboard at an angle of 45 degrees, outside the window, so as to reflect the skylight on the negative, will greatly help to overcome these difficulties.

When artificial light is used then a condenser is necessary. It is placed between the light and the negative so as to collect the light, in order to render the rays parallel, which enter it, so as to cause equal illumination of the negative. In this case the same apparatus can be used as described for daylight, so that an open light can be utilised if a large camera is used, but if not, then the light must be enclosed, and the enlargement thrown on an easel, as in the dark room arrangement. A good Argand burner answers admirably in place of the lime or electric light.

With regard to the exposure it will depend upon the nature of the light and size of stop used, and will best be found by trying on a small piece of paper first, and when the correct exposure is found for a certain size of enlargement and a certain stop used, then other exposures can be calculated by the ordinary tables of exposure, and the density of the negative taken into account. In the case of daylight, the light varies considerably, but when a correct exposure is found by experiment on a small piece of paper, allowance can be made for the weather the same as in taking negatives, and pretty accurate results obtained.

Development.

It is as well to fix upon a good developer for ordinary negatives, and try to expose to suit it, and, if a thin or flat negative is used, then a little more bromide added to the developer, so as to give contrast, and the exposure made to suit that developer, whilst a negative with great contrast should be given an exposure suitable for a developer with less bromide, so as to avoid exaggerating the contrast, so that exposure and development should be suited to each other. The exposure for artificial light will depend a great deal on the source of light used, but for daylight, and what I find is correct for this time of year (April), using stop *f*-24, at three in the afternoon, and Eastman slow paper, from quarter-plate to 10×8, as I have here to-night, I give three or four minutes, and develop with eikonogen, as follows:—

A.

Eikonogen	1 ounce.
Sulphite of soda	4 ounces.
Bromide of potassium	10 grains.
Distilled water	60 ounces.

B.

Carbonate of soda	3 ounces.
Distilled water	20 ,,

Use three parts of A, one part of B, two parts of water, and one drop of ten per cent. solution of bromide of potassium to each ounce of mixed developer.

From four to six prints may be developed in this developer in succession with ease, and the following fixing solution used after:—

Hypo	4 ounces.
Bisulphite of soda	1 ounce.
Water	20 ounces.

This fixing solution remains quite colourless if any of the developing solution should be carried into it by the prints, and prevents the possibility of any stains from the developer.

Ferrous oxalate is a very suitable developer, but is more troublesome to make and work with, having to have a clearing solution, and it has the disadvantage of becoming muddy when used with tap water by precipitating the lime, unless distilled water is used, and is, moreover, expensive.

Hydroquinone would be very suitable if it could be used with caustic soda or potash, but when these are used they are very injurious to the paper, as even a weak solution will rot the paper in a short time, so that it will not lift without falling to pieces, and if carbonate is used it is too slow. The above eikonogen developer is also excellent for plates, if used without the extra water, giving clean and brilliant negatives; but if one keeps to one developer, better results are likely to be obtained than when one is tried at one time and another at another, and the best way is, when you find a good developer, stick to it. FREDERICK PARK.

THE PRESENT POSITION OF PHOTOGRAPHY IN RELATION TO BOOK AND PERIODICAL ILLUSTRATION.

["Our Camera Club," Leytonstone, Essex.]

It is about twenty-five years ago since I heard the first whisper among wood-engravers of another Richmond in the field. For a long period engraving on wood had no rival in the production of relief blocks suitable to print with letterpress upon the ordinary printing machines, and, although this first process had nothing to do with photography, it had the merit of dispensing with the engraver on wood. I was but a boy in those days, but I shall never forget the hopeless state of alarm this simple process produced in the engraving world. It was a failure pure and simple, and to-day I believe is not used at all. This was the method. A block was made or chalk mixed with glue or some similar substance, on this a drawing was made by a material that hardened the chalk, now a brush was used to remove the chalk not affected by the material used, leaving the design in relief; this was electrotyped, and produced a block for printing purposes. It was called graphotype, and a poor, miserable thing it was, although from the talk of the promoters it was to do away with engravers altogether.

Many years passed away, and again the bogey turned up. Photographers had naturally been trying to find a cheap means of reproducing their pictures so that they could be sold after the manner of wood-engravings by tens and hundreds of thousands. Some one says there is nothing new under the sun, and some one modernised a very old process, well known among metal-engravers and colour printers, to stipple a plate of zinc or make a design upon it with a greasy substance, and eat away the untouched metal with acid, leaving the design in relief, etching being only the process reversed—that is to say, a plate of copper is coated with bitumen or some similar substance, and the design is scratched through it, exposing the bare metal, which is eaten out by the acid in which it is placed. Roughly, this is the mechanical engraving that we have to-day.

Antiquity of Wood-engraving.

It is now time I introduce photography, which had invaded the art of engraving long before process was thought of. Perhaps it would be best, so that I make myself perfectly understood, that I should sketch out what engraving on wood was before photography and process came into use. If you gentlemen respect old age, then wood-engraving will command your respect. So ancient is the art that we know wood blocks were used to stamp the bricks the Israelites made in the time of the Pharaohs. The Chinese have been engravers time out of mind, the engraver sitting on the floor with a little table over his legs to engrave upon. During the Middle Ages the art was kept alive, and splendid specimens are to be found among collections of knife work cut upon pear or similar wood. Albert Dürer and his pupils carried the art to great beauty, but it was left to an Englishman to place it in the front rank as the picture-gallery of the million. Bewick did this, and by leaps and bounds it has grown into favour. By its growth it has killed the army of splendid steel-engravers, the specimens of whose work will ever live as a monument of English talent. The great expense of the production, and the fact that it had to have a separate printing, and that a very expensive one, was fatal to it; what little chance is left for the steel engraver seems likely to die away altogether by the introduction of photogravure.

Bewick's Improvements.

The first idea in engraving by Bewick was to draw and engrave his own blocks, and boxwood was used instead of pear, gravers instead of knives; and one very important matter was that, instead of cutting the wood for the engraver, after the manner of a plank, it was cut across the grain after the manner of a salmon cutlet. The freedom this gave the engraver to cut right and left, up and down, or in circles, will be readily understood. As the art progressed, larger and larger things were attempted, and now came a difficulty. Good boxwood was only to be found, "except on rare occasions," in small sizes. Now came the skill of the wood-preparer, who managed to join two perfectly true edges by a tongue inserted in the two pieces, and glued up in a vice making one solid piece, and so things went on; but now a great awakening was to come upon the art, the idea of an illustrated newspaper came to the front, and blocks were required made in many pieces so that several workmen could at one time work upon them, the whole thing being screwed or glued together for the printer. I fear I shall tire you by this hasty relation of what engraving on wood consists of, but I deal with these particulars to enable you to understand somewhat the requirements of picture-making for our papers and books. One more step now came to the front, and that was electrotyping. As the numbers required of the printers increased, it was found necessary to have more than one machine going at the same time. Further than that, there was the danger of an accident to the wood block, it might split, it might get worn, and that after a few thousands had been printed if the wood was soft or not properly seasoned; so electrotyping just met this difficulty.

Electrotyping.

An electrotype is made as follows:—The wood block is put under pressure in a bed of wax making a mould. This has white metal run into it, which is afterwards put into a battery and a deposit of copper is thrown upon it. The result is a repeat of the wood block "if properly done." I say this, as in these cheapening days it is often shamefully scamped, and the engraver is blamed for results that are due to the electrotyper, or to the skimping price paid by his employer. By this means the wood block is not worked from at all—by "worked from" I mean printed from—but is kept in reserve should it be required.

Drawing on Wood.

Very soon after Bewick's time it was seen that, although there were talented men who could both draw and engrave their blocks, still there were men coming to the front who were engravers of a very high order, but were but poor draughtsmen, and at the same time artists were anxious to draw for engravers, and to-day, although there are a few instances of men who can both draw and engrave, in the majority of cases the drawing is by one hand, the engraving by another. Drawings were always made upon the block of wood with pencil and Indian ink, and of course, as the engraver cut away the design (turning it into a block for the printer's roller to go over it), bit by bit was lost. Now, it was here that photography came to the front. Drawing on boxwood was a technical art, and a very beautiful art it was and is. In the first place, everything has to be reversed—that is to say, the Lady Glendower signing the marriage certificate has to do so with the left hand, the design appearing in the periodical reversed; and if you gentlemen have ever painted or made a design you will know what agony it is to see it reversed in a looking-glass. This the wood artist had always to count upon, and was one of the difficulties that kept many artists outside book illustration; but now some enterprising photographer found he could photograph a drawing made upon paper, and print it upon the wood block *reversed*, the engraver having the original by his side when engraving. I remember all the miseries of these things, the thick and uneven films, films that when a man tried to cut a fine line flaked off a slice of the design, films that directly the ink roller was put over them worked up and filled up the lines with a sort of mud. In the finer parts the graver often had only cut the film, and the wood was intact. Bit by bit, however, these matters improved, but I say to-day much is to be desired, and the engraver has to watch the photographer like a cat does a mouse or he will find himself in for no end of trouble. I wish I had an audience of publishers to-night, that I might give forth the bleat of a

poor engraver, and tell them all we have suffered from photography on wood.

Now, in these days facsimile engraving was coming into fashion, and n art matters there is a fashion as much as in bonnets or dresses; the engraver had become a simple follower of the line laid down by the artist, he was the most clever man who followed slavishly the design without daring to think for himself; he had sunk his manhood, and become the bond-servant of an artistic master, certainly not lacking in impudence. When I look back on the designs of those days, I marvel at the simplicity of those who catered for the public, that public who can be led by the nose for a time by any stupidity. This age of cross-hatching, "or the bird-cage style of art," was the opportunity of the photographic process.

Zinc Etching.

So you see photography had got its foot in, and now the entire body was introduced to the shivering engraver. The publishing fraternity flew to the arms of the new love; prices began to be reckoned by square inches, no matter what the subject, it was all charged by the foot rule, the only stipulation being that the design should be drawn in line on Bristol board with black ink, and no erasure or muddle was allowed. I dare say some of these things have been altered, but only in small matters, and the system of producing was, and is to-day, much after this manner:—A negative is taken by the collodion process—a process, in my opinion, dry plates cannot hold a candle to, except for convenience and rapidity—and a zinc plate ground to a perfectly even surface, coated with albumen and a saturated solution of bichromate of potash, and evenly distributed by the plate being whirled round very rapidly, the surplus solution falling off; when dry, it is exposed under the negative till the perfectly clear lines are well printed; but the protected white is untouched by light. When the plate is sufficiently printed, it is removed and coated with ink; under the tap of water the free bichromate is washed away, that affected by the light—"the lines of the design"—being insoluble by the action of light. Now, with a clean roller, covered with lithographic ink—a greasy ink—the plate, being kept well covered with water, is rolled up again, and, if properly done, the design should be perfect, even to the most minute detail. I think you will at once see how easy it is in theory. A bath now of acid and water is prepared, and the zinc, protected by bitumen in all parts not wanted to be cut away also the back and edges, is placed in a wooden trough pitched inside, and the acid water poured over it in one even wave, and kept rocking till the surface has been eaten away, leaving the design just slightly in relief. Now, the acid has a knack of working after the manner of a scythe, and directly it gets under the surface it begins to undermine the delicate lines. To prevent this, the plate is taken out of the bath, inked up again, and warmed over a stove; being warm, it runs down the sides of the lines and so protects them from the acid; again and again this process is repeated, using softer ink; and a very delicate process it must be to prevent the fine lines being injured. There are two dangers to the publisher. The incompetent and cheap man will either lose the fine lines, or make them a series of dots, or else leave off the etching process before a sufficient depth is attained for the printer.

Screen Work.

This desirable state had been reached when again the publishing world was startled by a new departure in art matters, and this time it came from America. Our friends across the water had been working steadily upon the art of engraving, and now the American magazines became famous here, the great point being that a number of pictures were all jumbled together in one block, so that you had doubts whether the funnel of the steamboat in one picture was, or was not, the leg of the man in the picture above, further than that they were very fine—so fine in fact that English printers could not understand how ever it was possible to print them at all. Away went the brilliant publishers after the new craze, and the bird-cage draughtsmen were voted low and coarse, and the artist who could draw with lamp-black and Chinese white became a hero, especially if he could splice twenty pictures on a page; and, as for the engraver who could engrave very fine, he was, indeed, a treasure, and the printer became "for a time" more ill-used than ever all round. There was nothing for it but that he should get better machinery, the paper must be better, and blocks must be made really with greater knowledge and care, and better ink must be used. All this time the poor process man was going through a very rough time—like Othello, his occupation was gone; but now, with a courage very commendable, he set to work to tackle the drawings in lamp-black and Chinese white, and to-day there are many systems that profess to render a tone drawing; they vary slightly, but in the main are the same; the drawing is focussed in the usual way, but a screen of lines is placed between it and the sensitive plate; sometimes the lines of screen cross at right angles to each other, sometimes they are diagonal, the result being that in the negative the picture is cut into thousands of squares, and in the finished print on the zinc it is repeated; therefore the acid eats the lines away, leaving the design ut all over, and it becomes a printing block. You see, again, how simple it all is in theory. Let me clearly lay the position down here. On the one hand, we have the design requiring an engraver to render it for the printer, in the second process we do it by mechanical means, although the success depends upon the thoughtful and clever manipulation of the operator, and every part of the process must be very perfect, or the result is failure; this, so far as the line (or pen-and-ink drawing will, perhaps, make me better understood) is concerned, but as regards the tint, or wash-drawing, there are difficulties I must now deal with. Drawings in tone are made for photographing on wood of lamp-black, ivory black, or Indian ink, and Chinese white, some artists only using the white very sparingly, just to mark out a fold of a dress, or take a line off the face, any little matter in finishing that seems necessary; others use the black pure, as washes, in parts, and in other washes, to increase the charm of the drawing, an admixture of white, sometimes painting white upon white to trick the drawing, and give cheap finish; others mix every tone with white, and use the colour freely, killing the paper on which the drawing is made after the manner of thin oil painting.

Tom Symmons.

(To be continued.)

PHOTOGRAPHERS' ENGLISH.

The modern photographer, especially when of the amateur division is eminently and specially characterised by a certain *bonhomie*, which seems to find vent in a kind of missionary spirit—a desire to communicate in brotherly love, his private "experiences," struggles, and final victories, gained either by his own cleverness, or through some "new tip," or new form of apparatus or material, which he then nearly always terms a "boon." The way in which this word "boon" has been appropriated by the amateur photographic fraternity is remarkable. "Advantage," which it has replaced, has now no chance, at least among photographers.

"Utilised," for used, is another fine, round-sounding favourite.

Frequently, when an amateur is in great haste to communicate, he seems blind to the sad havoc he makes of the Queen's English, and, considering how very much the schoolmaster is abroad just now, and the vast sums spent by the State on schooling for high and low, it is really surprising to see so much want of knowledge of the native tongue even among persons possessing titles indicative of the fact that they have graduated at a University, or have been honoured by the fellowship of learned bodies.

I take a few instances to begin with from a recent publication. I have, in some cases, indicated by italics the parts I take to be erroneous.

First, we have a sample of queer English by one gentleman, who writes: "A still better plan I thought to have a frame made," &c.; then an example of odd etymology by another, who tells us "of development processes perhaps the most *favoured* is the slow bromide."

No doubt *favourite* is meant.

A third gentleman, who aims apparently at a style combining facetiousness with a *soupçon* of literary culture, writes:—

> "'Ask of the wind that *round about*
> With fragments *strew* the sea.'"

When will people cease to trust to their memories, and purchase quotation books?

A fourth, who gives his address as "India," writes: "*Some hand cameras* consist of *an* ordinary camera enclosed in a box."

I have myself a very "ordinary" camera. I have been wondering if, on enclosing it in a box, I might become the happy possessor of "some hand cameras." But, alas! I have no faith in such legerdemain.

Mr. Charles S. Patterson, at p. 131, gives "Hints on Medical Photography," which title, it appears, describes photography, not of medicals nor medicines, but of patients who constitute interesting or rare cases. Perhaps the opening sentence of Mr. Patterson, M.B., in recommending the flash light is the gem of the whole collection. He says, "The exposure is made so rapidly that transitory attitudes, or even slow *movements*, may be *portrayed*.' This splendid example of the method of conveying what one means by phrases of an exactly opposite signification betrays at once Mr. Patterson's nationality. He is evidently of Hibernian extraction.

Of course, no photographer ever "portrayed a movement." His

picture may have indicated motion, but that is what Mr. Patterson claims to avoid. And what is a "transitory attitude?"

A Mr. Mathews, who is evidently a strong adherent of the now half-forgotten Tichborne claimant, gives (p. 139) a good example of the grandiose and pedantic in "the transference having satisfactorily eventuated in the presentation of an unmistakable unison of the divided parts." In the vulgar tongue this means, "On interchanging the parts they were seen to match."

Observe the "transference" and "unison," used really for transposition and correspondence, as he is speaking of two portraits, one of Roger and one of Orton, which had been each cut in two, and the right-hand halves interchanged to see how they matched the remaining left-hand halves. The remarkable fact that the correct words are even longer than those used, suggests that this style of writer probably thinks more of sound than sense, and the first big round word that comes goes down, if it at all approaches the meaning.

Macbeth's wild war-shout, "The cry is still 'They come!'" seems hardly happy in reference to blisters on silver prints, p. 145. After the description of the very efficient method for getting rid of the blisters, it would have been trite and appropriate to add, "Come like shadows, so depart!" But let us hope Mr. Flamant was not really a reader of Macbeth.

Mr. Varley, F.R.A.S., gives us some remarkable science on p. 204. He says, "Light decreases as the square of the distance of the luminous body." This is lamentable, and from an F.R.A.S., too! Fill up the ellipsis, and it reads, "Light decreases as the square of the distance of the luminous body decreases." In other words, the nearer the candle the more in the dark. Truly, this may apply to the luminosity of the author in this particular case, but not in ordinary experience. Referring to some work of Dr. Wollaston, we are also informed:—

"The value of Sirius he gives as being that of one two-hundred-thousand millionth part of that produced from the Sun, the sun being equal to the light produced by 5763 wax candles burning at one foot distance from the screen."

In the first part of this curious sentence replacing Sirius by "the light of Sirius" makes at least sense. What the second part means is open to conjecture.

In a little work called the *Photographer's Systematic Exposure Note-book* I find the following curiosities under the heading "Tests for Water:"—

"Test for hard or soft water. Dissolve a small quantity of good soap in alcohol: if it turns milky, it is hard—if not, it is soft."

Hard or soft soap I suppose, since, though there is such a thing as hard drinking, who ever heard of hard or soft alcohol? and only soap and alcohol are mentioned. But what about the water we wanted to test?

Test for acid. Take a piece of litmus paper; if it turns red, there must be acid; if it precipitates on adding lime-water, it is carbonic acid. If a blue sugar-paper is turned red, it is a mineral acid."

Here is a wonderful piece of litmus-paper! It is to be "taken," whether "internally" or merely between the finger and thumb deponent sayeth not, neither are we informed what colour it may be at first; but "if it turns red there must be acid." Where? The next clause informs us. Evidently the paper is the acid. If "it" precipitate, "it" is carbonic acid. The pronoun clearly refers to the paper as in the first part of the sentence.

The last sentence of this noteworthy piece of scientific description defines a certain kind of mineral acid very neatly. This acid, according to our brilliant and lucid author, is a blue sugar-paper that is turned red. How it can be blue and be turned red at the same time is difficult to see, but this is no doubt one of the peculiarities of this particular mineral acid.

To say that all blue sugar-papers (by the way, what is a sugar-paper?) that are turned red are mineral acids does not, fortunately for science and the arts, imply that all mineral acids are blue sugar-papers.

J. BROWN.

Our Editorial Table.

THE BEGINNER'S GUIDE TO PHOTOGRAPHY. (4th Edition.)
PERRY, SON, & RAYMENT, Hatton Garden.

WHAT we have said of previous editions of this little work applies to that now issued. The information given is terse and practical, and easily appeals to the understanding of those for whom it is intended. At the present moment the chapter on "Hand Cameras" should be of special value. As an introductory guide to photography the work admirably fulfils its object.

THE April number of the *Manufacturers' Engineering and Export Journal* devotes a large portion of its space to an illustrated description of Messrs. Siemens' electrical works at Woolwich. The illustrations are many in number, and are from photographs by Messrs. Elliott & Fry and Negretti & Zambra. As examples of interior photography, we have seen nothing finer, but the process worker and the printer has done them scant justice.

THE DALLASTYPE SHAKESPEARE.
J. E. GARRATT & Co., 48, Southampton-row, W.C.

WE have received Part I. of a reproduction of the first folio edition of Shakespeare's works by Mr. Duncan C. Dallas. As a specimen of photographic reproduction the work is admirably done, and is well printed. This *facsimile* edition should find great favour among lovers of Shakespeare, and when complete will form a handsome and valuable addition to the library.

WITH the current number of *Judy* is presented a reprint of its first issue, which appeared on May 1, 1867. Curiously enough, No. 1 of *Judy* has a photographic joke. A bearded swell of the period has handed his lady cousin his photograph with the remark, "Good, is it not? I was done in Regent-street;" to which the lady (?) replies, "Oh, indeed! Done in Regent-street, was it? Done, certainly; but, cousin, it might have been done in the Zoological Gardens." From the quality of the humour one would never have supposed our "funny" contemporary would have lived a quarter of a century.

Meetings of Societies.

MEETINGS OF SOCIETIES FOR NEXT WEEK.

Date of Meeting.	Name of Society.	Place of Meeting.
May 9	Darlington	Trevelyan Hotel, Darlington.
,, 9	Dundee Amateur	Asso. Studio, Nethergate, Dundee.
,, 9	Norfolk and Norwich	Bell Hotel, Norwich.
,, 9	North Middlesex	Jubilee Hall, Hornsey-road, N.
,, 10	Derby	Smith's Restaurant, Victoria-street.
,, 10	Great Britain	50, Great Russell-st., Bloomsbury.
,, 10	Manchester Amateur	Lecture Hall, Athenæum.
,, 10	Stockton	Masonic Court, High-street.
,, 11	Leicester and Leicestershire	Mayor's Parlour, Old Town Hall.
,, 11	Munster	School of Art, Nelson-place, Cork.
,, 11	Photographic Club	Anderton's Hotel, Fleet-street, E.C.
,, 11	Reading	
,, 11	Stockport	Mechanics' Institute, Stockport.
,, 12	Birkenhead Photo. Association	Association Rooms, Price-street.
,, 12	Bradford Photo. Society	30, Godwin-street, Bradford.
,, 12	Camera Club	Charing-cross-road, W.C.
,, 12	Cheltenham	
,, 12	Hackney (Annual)	Morley Hall, Triangle, Hackney.

,, 13	West London	Chiswick School of Art, Chiswick.

LONDON AND PROVINCIAL PHOTOGRAPHIC ASSOCIATION.

APRIL 28.—Mr. S. J. B. Wollaston in the chair.

Messrs. H. Heather and T. Stevenson were elected members.

A question from the box was as follows:—"Can permission be obtained to take photographs in the British Museum; if so, to whom shall I apply?"

Mr. T. E. FRESHWATER said it was necessary to apply to the heads of departments in which the objects wanted to be photographed were placed.

A second question asked whether an intensifier that had been recommended was a good one. It consisted of bleaching with mercury, followed by caustic soda.

Mr. W. E. DEBENHAM doubted the permanency of the results unless sulphide were used to blacken the image.

Mr. J. BARKER said he had used mercurial intensification for twenty-five years, and had found simple washing sufficient to ensure permanence. He did not know when the results he had got would fade. He bleached right through, washed well, and treated with ammonia. Images only bleached superficially were fugitive. He washed for seven or eight hours, and never for less than four.

Mr. J. E. SMITH said that he had intensified with the formula quoted as well as with one having ammonia instead of the hydrate. The ammonia gave the darkest and best images for his purpose (copying pencil drawings), in which he wanted to get as much blackness as possible.

Mr. W. E. DEBENHAM recommended for the purpose iodide of mercury, followed by Schlippe's salt.

A third question was: "Is there a spectacle lens that can be used in con-

junction with a doublet of nine-inch focus that will reduce the focus to about half; and, if so, what number is it? Where should it be placed, in front, behind, or between the lenses?" The answer was a nine-inch spectacle lens should be used, and placed in the middle of the lens.

Mr. J. S. TEAPE had made experiments with a sample of the non-actinic medium shown at a previous meeting by Mr. F. A. Bridge, and found it excellent as a protective medium for the light of the dark room. He had made a number of holes in a piece of opaque material, behind which he had placed various thicknesses of cherry and golden fabric, as well as one thickness of the new material. An Ilford plate was then placed in contact, and magnesium ribbon burnt. Development of the plate showed that the new material was quite safe as compared with the other substances. It passed a great deal more light.

Mr. W. H. SMITH (of the Platinotype Company) demonstrated the new cold bath platinotype paper, developing a number of prints from negatives by Messrs. Drage, Frith, and Edwards. He said the only difference between this and the other papers was in the development, the developer being exactly the same as used in the hot-bath process, but used cold. A cold developer was much handier to employ, and, if its temperature even went so low as near freezing, it made little difference. The loss from evaporation was very slight. The prints took longer to develop, but air bubbles were got rid of entirely. He left a large undeveloped patch in the centre of a print for several seconds; upon development no mark could be seen. Finger-marks, made by the developer on undeveloped prints, did not show when the whole of the print was developed. With the other papers, if they were folded before development, white lines appeared; this paper could be broken or folded without any such lines appearing. Mr. Smith also showed practically that development could be localised, and accomplished either by the fingers or a brush. He said that with the new paper the blacks were better than those given by the old, and, indeed, results generally were better, as they could see. Under-printed pictures could be improved by warming the bath, which could be done up to 130°. The effect of weakening the developer would be to prolong development.

Mr. P. EVERETT asked whether the sensitising solution alone could be procured, so that, if necessary, additional work could be placed on a print?

Mr. T. BOLAS said that a wash of Indian ink would be preferable.

Mr. SMITH said another deposit could be obtained on a developed print in the way Mr. Everett suggested, but it would be necessary to wash the developer off, dry, sensitise, and expose again. In "clearing" prints, he advised a final washing in solution of carbonate of soda to neutralise the acid. All the other manipulations of the new paper were the same as the old

In moving a vote of thanks to Mr. Smith for the demonstration, the Chairman, as one of the oldest platinotype printers, said the advantages of the new paper were enormous. Finger-marks would not show, damp and "breakages" produced no effect, and the printing in of clouds had been simplified. It was a power to be able to develop with a brush. There was also another advantage, in crystals of the developer not now depositing, as in the hot-bath process.

Holborn Camera Club.—April 29, Mr. Fred. Brocas in the chair.—Mr. R. Luxton gave a demonstration on *Photo-mechanical Work*, this being, perhaps, one of the first of its kind ever given before a club of this description. Mr. LUXTON showed the various stages of the process, viz., 1, the making of the solution to coat the plate; 2, passing the plate through a bath of acid and alum; 3, coating the plate with albumen; 4, printing on the zinc, and developing the image; 5, rolling up the plate for etching; and, last, etching the plate. The demonstrator went through the different stages in their turn, showing very clearly the manner in which the work is done. He gave various hints which he had learned from his long experience of the work, and thoroughly interested the members present with one of the most practical demonstrations which have been given before the Club.

Hackney Photographic Society.—April 28.—The American lantern slides were exhibited. Samples of the Imperial Dry Plates were handed to the members by the Hon. Secretary, with a request that results were shown and opinions given. The Club Album, containing portraits of the members, was placed on the table. The rest of the evening was set apart for sale and exchange of apparatus, the idea being that many members had things which were not of service to them, and an exchange would be more mutually pleasing. The next meeting will be the Annual General Meeting.

Putney Photographic Society.—April 30, last meeting of winter session, Rev. L. Macdona in the chair.—There was a very fair attendance to witness the lantern slide competition, which resulted as follows:—Class A, Landscape: 1, Mr. A. E. Smith; 2, Mr. William Martin, jun. Class B, Seascape: 1, Mr. A. E. Smith; 2, Mr. L. S. Zachariasen. Class C, Portraiture, &c., 1, Rev. L. Macdona; 2, Mr. Wm. Martin, jun. Mr. Cembrano, of Richmond, officiated as judge. Great satisfaction was expressed with the samples of the new Imperial Dry Plates, distributed at the former meeting, capital results having been obtained. The Annual General Meeting will be held on May 11.

Richmond Camera Club.—April 22, Mr. Cembrano in the chair.—Mr. F. Hollyer gave a demonstration of platinotype printing with the new cold-bath paper. On April 29 Mr. A. T. Hare exhibited an optical lantern, designed and made by himself, which presented many novel and ingenious features, and was adapted for every class of projection, from the ordinary slide to the most delicate scientific experiment. Mr. Cembrano then gave an address on the subject of *Development en route*, setting forth the advantages of developing, at any rate, a good proportion of one's holiday pictures before returning home, explaining his *modus operandi*, and alluding to some of the difficulties he had met with, especially in French and Spanish hotels, where water is doled out by the pint. Members made notes and resolutions—with what practical result the coming summer will show.

Croydon Camera Club.—April 25, the President (Mr. H. Maclean, F.G.S.) in the chair.—Mr. J. R. WHITE gave a description of the construction and method of using the optical lantern, and its various adjuncts, illustrated by experiments and demonstrations. The President drew members' attention to an article by Mr. J. A. Hodges on the after-treatment of negatives, and shortly described the *modus operandi* suggested, illustrating his remarks by two process prints, showing the beneficial effects produced by the means employed. On April 30, the first Club excursion of the season was held, when a party of fifteen, conducted by Mr. H. Maurice Page, visited Oxted, and spent a busy afternoon amongst the attractive scenes of this vicinity. On Monday, May 9, Mr. E. J. Wall will lecture at the Club-rooms, 56, George-street, on *Development*.

Bath Photographic Society.—April 27, Mr. Austin J. King in the chair.—The CHAIRMAN said the first business of the evening was a notification by the Secretary of the decease of their good friend and member, Mr. John Dugdale. Since the foundation of the Society he had worked steadily for its welfare, by giving lantern-slide exhibitions, and in other ways contributing to the interest of the meetings. Throughout a long life in Bath he had been greatly respected. The Chairman then spoke of the arrangements made by the sub-committee regarding the Exhibition of Photographs in conjunction with the Floral Show announced for May 18 and 19, and he was pleased to say that their sub-committee were able to report that the Floral Fête Committee not only coincided with the conditions stipulated, but placed themselves almost unreservedly in the hands of the Society. He thought a most successful result would be achieved. The Chairman then vacated the chair, in order to deliver his promised lecture, *With the Camera in Spain*. Critical examination of summer outfits, and laying aside for the coming winter of enlarging apparatus, reducing cameras, lantern-slide paraphernalia, &c., were amusingly portrayed. Plentifully equipped for all sorts of subjects, and full of hope in the achievement of a rich harvest of negatives, the lecturer took an adieu of this country when the Thames wore a dense mantle of yellow fog, to penetrate which colour sensitive plates did not avail. The dream of snap-shots on an ocean-going steamer was again dispelled. Then followed rigid regulations against the camera in the neighbourhood of Gibraltar. These and other difficulties were encountered until the photographer's El Dorado was reached, the beautiful, the unique Alhambra. The lecturer's description in the first place was technical from a photographic point, he then entertained his audience with details of a general character, dating back from the earliest history down to the present day. Speaking of bull-fight photographs, Mr. King said the reason such illustrations were rare was due, not to the rapid movements of the actors so much as the large area over which the fight was enacted; thus the principal objects were by distance minimised. The President hoped his paper would open discussson, especially on film photography, a subject which the Chairman, of all others, could ventilate. The CHAIRMAN remarked that he preferred the celluloid films of considerable substance used as plates are in the camera and separated by cardboard. Roll holders he did not fully appreciate.

Liverpool Amateur Photographic Association.—April 28, Mr. W. Tomkinson in the chair.—Four new members were elected. The President announced that very satisfactory arrangements had been made with respect to the new club-rooms, and the work of fitting up would be proceeded with as soon as possible. He also stated what had been done in the way of arranging excursions for the season, and gave an account of the annual dinner, which had taken place at the Adelphi Hotel on Monday, April 25. His Lordship, the Mayor, was present on the occasion, and expressed his willingness to become a patron of the Association. The dinner was one of the most successful and enjoyable that had been held. Mr. J. T. Norman-Thomas reported on the excursion to Crosby and Ince Blundell, at which upwards of eighty persons were present, and something like 450 exposures were made. Some of the work was on exhibition at the meeting, and was of excellent quality. Some stereoscopic slides and monthly competition prints for January were exhibited during the evening. Several novelties were shown, and a number of members' slides were passed through the lantern. On the motion of Mr. B. J. Sayce, the recommendation of the Council, that Mr. H. P. Robinson be elected an honorary member of the Association, was unanimously adopted.

Newcastle-on-Tyne and Northern Counties' Photographic Association.—April 25, Mr. John Watson in the chair.—The outdoor meetings were arranged, the places selected being Stocksfield, Down the Tyne, Gilsland and Naworth, and Wark. Mr. F. Park then read a paper on *Enlarging* [See page 297], illustrating his remarks by a photograph of the apparatus employed, and by a series of finished enlargements of very superior qualities, afterwards developing several others by means of eikonogen.

South Manchester Photographic Society.—April 25, Mr. W. I. Chadwick in the chair.—Messrs. J. J. Arnold, H. J. Reid, E. Tarbolton, A. E. Tysoe, and H. Worthington were elected members. Prints from negatives taken at the previous meeting by magnesium flashlight were exhibited, and one exposed by the Hibbard flash-lamp was pronounced decidedly the best, and proved to all present that, with judicious management and a little experience, admirable portraits were quite possible, as the exposure in this case had been quite sufficient. Other lamps of the duplex form were not considered to possess any greater advantages. Members had been invited to bring specimens of their work done during the Easter holidays, but, owing to the shortness of the time, not many results were shown. Mr. Chadwick exhibited about thirty stereoscopic transparencies, made on Thomas's ground-glass plates, and developed with eikonogen. These were handed round to the members with a suitable stereoscope. They were much admired, and it was remarked that an additional ground-glass backing was a wonderful improvement. One view in strong sunlight, taken "against the sun," Mr. Chadwick had printed very deeply, and, by the addition of a pale blue glass backing, a delightfully realistic moonlight view was the result. Another highly interesting slide was one taken from the Menai Suspension Bridge, showing the ironwork in the foreground, with a landscape of the Straits in the distance, and demonstrated in a wonderful manner the great advantages of stereoscopic pictures over all other photographs. The whole of Mr. Chadwick's transparencies were printed by gaslight, and developed in one evening. Mr. Bowden exhibited a lanternscope, which is intended for use in viewing lantern slides; but, when a lantern slide and a stereoscopic slide from the same negative were compared, the difference was undoubtedly in favour of the stereoscopic one. An outdoor meeting was arranged to take place next Saturday at Miller's Dale.

Edinburgh Photographic Society.—The first out-door Saturday ramble for the season was held on April 30. Linlithgow Palace and its surroundings was the place chosen for this day's work. The palace itself is a picturesque ruin, situated in the heart of the small town, and overlooking a small lake, and it affords many fine views, as well as bits of ruined architecture of the best period of Scotch baronial taste. On the same day a number of members of the Edinburgh Architectural Association (some of whom are also of the Edinburgh Photographic Society) were present, meeting with the Provost, magistrates, and several members of the Town Council, making a minute survey of the ruin, with the view of commencing some necessary repairs, if not restoration of the entire fabric, which was destroyed either purposely, carelessly, or accidentally, while in occupation by the troops under the Duke of Cumberland, while putting down the Stuart attempt by Prince Charlie in 1745. A small sum has been voted in Parliament for the purpose, but much more will be required to make the old Scottish palace anything like what it was—one of the finest buildings in the country. The day was a fine but very breezy one, and this gave some discomfort to several of the lighter-equipped members of the party, but on the whole a very pleasant day was spent, and many good pictures secured, several with fine cloud effects. Full permission had been granted by Mr. Robertson of H.M. Board of Works to go over the entire building and grounds, and photograph whatever was of interest. There were about twenty members present with their cameras.

Leith Amateur Photographic Association.—April 26. Mr. Smith (Vice-President) in the chair.—A paper was read by Mr. L. C. Abbot, entitled, *Notes on Isochromatic Plates*, in which he gave his experiences with them in the field. He stated that he could not as yet give a definite opinion on their superiority over the ordinary plates, as that would require a much longer trial than he had been able to give; but, so far as he had gone, the results were fairly satisfactory and such as to induce a much more extended trial. A brief discussion ensued, and several questions were asked, to which Mr. Abbot replied. It was announced by the Chairman that the Committee had agreed to have an outdoor meeting on the Queen's birthday, and that the Association had received full liberty to photograph in the grounds of Raith House, Kirkcaldy, the demesne of Mr. Munro Ferguson, of Novar and Raith, the M.P. for the Leith burghs, and he trusted that they would have a good day, and a capital turn-out of the members. This concluded the business, and the meeting adjourned.

Photographic Society of Philadelphia.—April 13, Annual Meeting, the President, Mr. John Bullock, in the chair.—The appointment of the following Special Committee on Standards was announced:—Professor Benjamin Sharp, Messrs. George W. Hewitt, Theodore H. Lauers, Lewis T. Young, and William H. Walmsley. During the year six members had been lost by death, thirty-four new members were elected, the total number now on the roll being 200, or about the same as at the date of the last report. In view of the fact that the annual dues had recently been doubled, this fact was considered very gratifying. The election for officers and directors for 1892-93 resulted as follows:—*President:* Mr. Joseph H. Burroughs.—*Vice-Presidents:* Messrs. Edmund Stirling and Charles R. Pancoast.—*Directors:* Messrs. John C. Browne, Charles L. Mitchell, M.D., John G. Bullock, William H. Rau, Frederic E. Ives, Samuel Sartain, George M. Taylor, and John Carbutt.—*Treasurer:* Mr. George Vaux, jun.—*Secretary:* Mr. Robert S. Redfield. An illustrated lecture was given by Dr. Benjamin Sharp, his subject being *A Trip through the West Indies*, which was followed by a demonstration of the process of making lantern slides with gelatine dry plates.

Correspondence.

☞ *Correspondents should never write on both sides of the paper.*

"PHOTOGRAPHIC PORTRAITS."

To the EDITOR.

SIR,—Mr. Cimabue Brown, jun., appears to flatter himself with the delusion that I imagine his pseudonym to "veil a distinguished identity." I have not the remotest idea concerning his individuality, but I should certainly never dream of suspecting him of being distinguished in any way. My endeavour was to draw attention to a reprehensible practice in photographic journalism, and I was not disinclined to avail myself of the co-operation (however, otherwise, it might be qualified) of Mr. Cimabue Brown, jun. Having succeeded in my object I have no further use for him nor interest in him. If, therefore, he continues individually to emphasise the practice referred to, I shall not complain. So far as I am myself concerned the incident is closed.—I am, yours, &c.,

Sunbury, May 3, 1892. ALFRED MASKELL.

[We terminate this correspondence, into which we cannot help saying that our good friends have imported considerable acrimony and uncalled-for hard hitting, by quoting from a letter which we have received, in reference to Mr. Cimabue Brown's statements in our last issue, from Messrs. Steadman, Van Praagh & Sims, solicitors. These gentlemen inform us that our correspondent's letter conveys either that some member of the trade has bribed their clients, the proprietors of the *Optician*, to write a certain style of photographic work down, or that he is pecuniarily interested in the paper. They state that rumours to this effect have been in circulation for a considerable time, and we are asked to say that neither the gentleman referred to in Mr. Cimabue Brown's letter, nor any other person whatever, has, besides the proprietors, directly or indirectly any interest in the *Optician*, or has taken any part whatever in the conduct or affairs of that journal. We are happy to comply with the request of Messrs. Steadman & Co., who are also good enough to offer us facilities for assuring ourselves of the absolute truth of their statement, the accuracy or inaccuracy of which, however, is Mr. Cimabue Brown's concern alone, and not ours.—ED.]

PUBLICATION OF PATENT SPECIFICATIONS.

To the EDITOR.

SIR,—As you always give great prominence to the patent applications and specifications connected with photography—a feature of the JOURNAL which I, no doubt in common with many other inventors and patentees, highly appreciate, will you allow me a line of space to complain of the slipshod manner in which the publication of the *Patent Journal* has lately been conducted? Nominally it is due at ten o'clock on Wednesday morning, but as a rule it is late in the afternoon before it appears, and sometimes it is not accessible till Thursday morning. Cannot some M.P. ask a question in the House on the subject?

May I also suggest to the authorities of the Patent Office the provision of a simpler plan for enabling one to ascertain what applications have been made during the current week, pending the appearance of the *Patent Journal*? At present, if one wishes to find out what applications have been made in connexion with a particular subject, it is necessary to hunt through many hundreds of slips of paper placed in little pigeon-holes, alphabetically arranged according to the names of the applicants, a process which consumes a fearful and wonderful amount of time. Surely it would be better to provide a book with a cross index of names and subjects for the purpose.—I am, yours, &c., PATENTEE.

Stoke Newington, May 4, 1892.

[Our correspondent's letter reaches us at a moment when we have reason to indulge in complaints similar to his. We do not doubt that the authorities of the Patent Office library will take steps to remove the inconvenient system at present adopted there. We hope also that the publication of the *Patent Journal* will in future be arranged with a better regard for punctuality and regularity.—ED.]

ACTINOGRAPH SPEED OF PLATES.

To the EDITOR.

SIR,—I can quite endorse every word uttered by Mr. Carter Browne in last week's issue on the above subject. I have been trying for some time to get the correct speed for the Ilford Ordinary plates, as per Hurter & Driffield's actinograph. I have applied to the makers of the plates, also to Messrs. Hurter & Driffield, the makers of the actinograph, but cannot obtain the information, and, being quite satisfied with the brand of plates I am using, I would not like to have to change to any other. While the plate-makers are considering the matter over, perhaps some of our willing helpers might give us their experience.—I am, yours, &c.,

April 30, 1892. H. PYNE.

HONOUR TO WHOM HONOUR IS DUE.

To the EDITOR.

SIR,—My attention has just been called to a report, in your issue of April 29, of the doings of the North Wales Amateur Photographic Society, in which the following passage occurs:—"One view of Gloddaeth Hall is very fine indeed, and, in order to obtain it, Lady Mostyn had a lofty stage erected, under Mr. Slater's direction, for him and his camera."

As a matter of fact, the stage was erected for Mr. Edge, of this town. Acting upon the suggestion of Lord Mostyn, and by the kind permission of Lady Augusta Mostyn, I made use of the stage in order to obtain a photograph for the album which was presented to the Queen of Roumania by the people of Llandudno.

It is quite true that I obtained several good negatives of Gloddaeth Hall, but not one of them was taken with a rapid rectilinear lens.—I am, yours, &c., J. SLATER.

Llandudno, May 3, 1892.

[We have also received a communication from Mr. T. Edge, of Llandudno, drawing attention to the error which Mr. Slater points out.—ED.]

Exchange Column.

*** *No charge is made for inserting Exchanges of Apparatus in this column; but none will be inserted unless the article wanted is definitely stated. Those who specify their requirements as "anything useful" will therefore understand the reason of their non-appearance.*

Wanted, good studio stand in exchange for background.—Address, E. V. WILLIAMS', 3, Bellvue-terrace, Southsea.

Will exchange whole-plate tripod folding stand, two backgrounds, interior and exterior (cloth), and two volumes *Amateur Photographer*, 1890 and 1891, for show-case, size about 30 × 20.—Address, J. WARE, 40, High-street, Atherton, near Manchester.

Answers to Correspondents.

All matters for the text portion of this JOURNAL, *including queries for "Answers" and "Exchanges," must be addressed to* "THE EDITOR," *2, York-street, Covent Garden, London. Inattention to this ensures delay. No notice taken of communications unless name and address of writer are given.*

*** *Communications relating to Advertisements and general business affairs must be addressed to* "HENRY GREENWOOD & Co.," *2, York-street, Covent Garden, London.*

PHOTOGRAPHS REGISTERED:

W. H. Fischer, Withington, near Manchester.—*Photograph of His Grace Herbert, Archbishop of Westminster.*

W. C. BAX.—We have no knowledge of the matter. Write and threaten the man who is personating you with legal proceedings.

F. G. S.—The firm referred to is of high standing, and would not, we are sure, make claims for the camera which it does not possess.

F. P.—We cannot trace the particulars. The Air Brush Company has no agent in this country. Communicate with Mr. J. J. Atkinson, of Liverpool.

W. W. SMITH asks for a good pyro and ammonia developer where the pyro is used dry and the ammonia ·880 by itself.—There are many such formulæ in the ALMANAC for 1892.

PRINTER.—If the fixing and subsequent washing were properly done, there would possibly not be any difference in the permanence of the results of fixing a washed and an unwashed silver print respectively.

CAMBS.—1. We are not acquainted with any book dealing with the working up of black and white enlargements. 2. Place yourself in communication with Mr. Redmond Barrett, of 50, Kellet-road, Brixton, S.W.

PUZZLED.—As you do not sufficiently describe the effect obtained by your present system of lighting, it will be better if you will send us two or three unmounted prints illustrating this. We can then be able to advise.

JOHN LEWIS.—At first sight, we should say that the varnish mentioned was bound to darken by heat; but pending our making a trial of it, would you kindly indicate the page of the JOURNAL where it was recommended?

CONCENTRIC.—We cannot explain why your lens works sharply on portraits and is imperfect for lenses unless we saw it. But if it fails to give a sharp landscape without the employment of a stop, then we advise you to use a stop.

PYRO (Johannesburg).—We are unable to help you in the matter of high charges made for the JOURNAL and ALMANAC by South African booksellers. Why not subscribe direct? We should be pleased to have the promised notes.

COL. GUBBINS.—We think your suggested remedy of squeegeeing the negatives on to glass the best available, and should not think the sizes or shapes would be altered in so doing. From the print sent we should say the original negative was excellent.

J. ALLEN (Penrith).—There is no absolute rule for determining the distance to which the lenses on a binocular camera should be separated from each other; but, for such sizes as half-plates, it is expedient to fix them as nearly as possible opposite to the centre of each half of the plate.

H. K.—We are scarcely in a position to advise as to the comparative merits of the two lenses mentioned, never having seen the No. 1 on your list—we refer now to utility for general purposes; but we here endorse all that we said on behalf of the latest entrant into the field.

C. PANEL.—The cause of the stain on the panel picture is that some of the colouring matter of the mount has penetrated it. If you will cut a mount in two, you will see that one of the upper sheets is exactly of the colour complained of. If using these mounts in future, employ a waterproof mountant.

J. B.—Electro casts can most undoubtedly be obtained from gelatine moulds. The surface may be rendered "conducting" in a variety of ways; plumbago and bronze powder answer well, but it is probable that sponging over with a solution of nitrate of silver (largely alcoholic), and then reducing the metal by any of the well-known methods, will answer better for the most delicate class of work.

STUDIO writes: "Would the local board require a plan for a studio on the main road if laid on the ground like a canvas tent, or could they demand a plan or refuse to allow me to put a canvas tent, fastened with stakes in the ground, if the owner of the ground gave me permission to do so?"—Probably not, as the studio would only be temporary; but we should recommend you to consult the local surveyor in the matter.

NEMO.—In the aniline process paper was coated with a sensitising solution, consisting of—Potassium bichromate, thirty grains; phosphoric acid solution, one fluid drachm; water, one fluid ounce. Expose behind a transluscent positive in the ordinary printing frame for about a third of the time required by silver paper. Develop with the vapour of aniline, made by mixing one drachm of commercial aniline with two ounces of benzole. Wash in plain water, and afterwards in water acidulated with sulphuric acid. The process cannot be worked on glass.

F. T. says:—"I have invented an exposure meter which is automatic in action, giving the plate correct exposure in any intensity of light. It could be applied to any ordinary camera, would be cheap, light, and portable. I should be greatly obliged if you would give me your candid opinion as to whether you think this invention would be worth protecting by letters patent, also if such a thing has been done or tried before."—There are several exposure meters in existence, but we do not think any of them are fitted to an ordinary camera. We could not say whether our correspondent's invention is worth protecting without first having some particulars of it.

ORION.—While we recommend you to save yourself the trouble of making potassic oxalate by purchasing it ready prepared, yet is its manufacture a matter of extreme simplicity. Make a saturated solution of carbonate of potash, and add to it oxalic acid until effervescence ceases, and—there you are. If you prefer having it in the crystallised form, pour it out in a flat dish, and allow the liquid to evaporate.

FADED PRINT writes: "Will you examine the enclosed photographs and tell me what is the cause of their going in the way they have? These, with a number of others, have been in a show-case a few months, and all have gone more or less. Is it, first, the mount which causes it? or, secondly, the possible dampness of the wall where case is fixed, as it is outside in an exposed situation? or something wrong in the manipulation? If the latter, what is it?"—In reply: Probably the hypo was not entirely removed from the prints in the final washing, and the damp has reacted upon the little that was left in them and caused the fading. Had the pictures been kept in a perfectly dry place, they would not have changed. We do not think the mounts are *ab initio* at fault, but you put them to a very severe test.

SILVER.—Assuming the silver to be pure, it should be placed in a beaker, and strong nitric acid, sp. gr. 1·4, poured on it in the proportion of three-quarters of an ounce of acid to each ounce of metal; dissolve by heat; pour into an evaporating basin, and remove the excess of acid by boiling. Redissolve the crystallate in a small quantity of distilled boiling water, and, on cooling, crystals of silver nitrate will deposit. For gold chloride, dissolve the metal in a hot solution of *aqua regia* (hydrochloric acid, three parts; nitric acid, one part). Remove the excess of acid by evaporation, dissolve the gold chloride in boiling water, add a solution of ferrous sulphate until a precipitate is no longer produced, and wash the precipitate on a filter with boiling water until the wash-water no longer yields a precipitate with barium chloride. Redissolve the gold in *aqua regia*, and evaporate to dryness. It would, however, be cheaper and more convenient for you to purchase the salts ready prepared.

THE PHOTOGRAPHIC CLUB.—May 11, *Fancy Printing and Mounting.* 18, *Reversed Negatives.* Outing, Saturday next, May 7, Carshalton. Train from London Bridge, 2.18.

PHOTOGRAPHIC SOCIETY OF GREAT BRITAIN.—At the meeting on Tuesday, May 10, Mr. W. J. Harrison will read a paper on *A Proposed National Photographic Record and Survey.* Members of affiliated Societies are invited to attend.

LONDON AND PROVINCIAL PHOTOGRAPHIC ASSOCIATION.—May 12, Members' Open Night. 19, Monthly Lantern Night; last of the season. 26, *The Photographic Study of Clouds and Lightning*, illustrated by slides, Mr. A. W. Clayden.

MESSRS. MAWSON & SWAN inform us that, owing to the serious fire which occurred at their Newcastle warehouse on Wednesday evening, April 27, their business will be rather seriously inconvenienced for a few days. For the present, however, all orders will be attended to by their London house, and they ask the indulgence of their friends in the meantime.

MR. G. L. ADDENBROOKE is to read a paper at the Society of Arts on Wednesday next, the 11th inst., on the *Uses and Applications of Aluminium*, a subject to which he is known to have given a good deal of attention lately. The application most interesting to our readers is that of the use of this metal for the construction of lens mountings and camera fittings, and no doubt Mr. Addenbrooke will have something to say on this part of his subject. Photographers who wish to attend the meeting can obtain cards of admission if they will apply to the Secretary of the Society of Arts.

MESSRS. MARION & CO. write that, in consequence of the continued success of the "Radial" camera, and from many inquiries for other sizes, they now make it for lantern size and for half-plate size, both carrying twelve plates, as in the original quarter-plate one. The three-and-a-quarter square (lantern size) is very light and compact, and well suited to ladies' use. Although Messrs. Marion recognise that a half-plate hand camera is a somewhat bulky instrument, yet the "Radial" is far lighter, compacter, and more portable than a folding camera with six double backs, shutter, &c.

CHICAGO EXHIBITION.—One of the most interesting exhibits likely to be made by the British Commission at the Chicago Exhibition, will be a large scale map, showing the discoveries which have been made in North America by Englishmen. Though Columbus discovered the West Indies, the credit of first sighting the mainland of America seems—if we put aside the unrecorded investigations of the Northmen—to be due to an Englishman, Sebastian Cabot; and the list of names of English explorers of America, which is headed by his, is a very long and distinguished one. Raleigh, Sir Humphrey Gilbert, Sir Hugh Willoughby, Frobisher, Davis, Hudson, Baffin, in the seventeenth century, were followed, in the eighteenth, by Scoresby and Cook; while the work they commenced was carried on during our own century by the Rosses, Parry, Franklin, Collinson, Maclure, McClintock, Nares, and Markham. It will, therefore, be seen that there is ample material for a map such as that proposed.

THE BRITISH
JOURNAL OF PHOTOGRAPHY.

No. 1671. Vol. XXXIX.—MAY 13, 1892.

THE KEEPING PROPERTIES OF ROLLABLE CELLULOID FILMS.

At the commencement of a new photographic season the subject of dry plates *versus* celluloid films is one that claims attention. It is not our intention here to institute comparisons, tending to give one an advantage over the other, but rather to confine ourselves, in the main, to an investigation of the subject of films, with special reference to their keeping properties.

We may as well here say that our experience of films wound in roller slides or roll holders has been practically confined to the productions of the Eastman Company, who established themselves among us about seven years ago. About that time, or rather anterior to that time, we had a spool of the Company's sensitive negative paper wound in New York for a 10 × 8 camera, which circumstances prevented our making use of until the Glasgow meeting of the Photographic Convention in July 1887; and it is gratifying to be able to record that, after being kept so long, every exposure made with it yielded a perfect negative. And, although the world was running wild after methods for rendering the paper negatives transparent, in order to hasten the printing from them, and, as some imagined, to destroy the grain of the paper, our negatives were printed from just as they were, no signs of granularity being visible in the prints.

We mention this chiefly because both then and now are to be found hypercritical persons who maintained, both with regard to the negative paper of those days, the stripping film by which it was succeeded, and the flexible celluloid film of the present period, that neither would keep; this last, because the materials employed in making the celluloid film itself were destructive to the salts of silver used in the sensitive film. For ourselves, we never could see any good reason for these predictions, and, so far as they applied to paper, we have quite disproved them.

As respecting the celluloid film, we are enabled to speak of it through the experience of another, an old and well-experienced friend, Mr. W. J. Stillman, of Rome, for we have just seen a large number of 10 × 8 negatives made by him from a roll of the Eastman Company's celluloid film, which Mr. Stillman declares has remained untouched in his Eastman roller slide for more than two years. These negatives are most beautiful in every respect, being free from defects due either to atmospheric or mechanical causes, and we do not grudge our high meed of credit to the Eastman Company for having become the practical pioneers of film photography, and for having, single-handed, accomplished, and reduced to every-day practice, a system of film photography, having within itself all the essentials for success.

Before concluding, let us examine the condition of the film, in virtue of which it seems reasonable to expect it to keep good for an indefinite period, far exceeding the examples cited; and we are not here speaking of the ordinary celluloid film, so called, which is thick, and intended to remain flat like a glass plate, but of the *rollable* film. This is a thin, transparent, flexible preparation of celluloid, having one side coated with a sensitive silver emulsion; and the intention of the makers is avowedly to enable it to be wound upon itself in the form of a roll. At first sight, one does not realise that this method of winding, or rolling the film upon itself, can have any other object than to enable it to be conveniently transported and used in a roller slide; but, upon further thought, one will see that an equally important feature of this method of packing is that the successive convolutions of the rolled film form each upon the other an impervious envelope of inert matter, unaffected entirely by changes of temperature or of moisture. The rollable film thus packed is, in our opinion, in the most perfect form possible for preservation from injury of any kind. And if it be placed within a roller slide, made so as to maintain it in the condition in which it leaves the manufacturers' hands—such a slide as that issued by the same makers—we cannot see aught to prevent its remaining good, and ready for use, during a long term of years.

AERIAL PERSPECTIVE—THE TELE-PHOTO LENS.

We might first of all demur to the strict legitimacy of the above term, for perspective true and proper, which is the science of representing solid objects on a flat surface, ought not to have anything to do with atmosphere; but, as the term aerial or atmospheric perspective has for a long time been in common use by artists to signify a well-known effect, we too employ it in its popular sense. It means the influence of the atmosphere, laden as it usually is with finely divided matter, in obliterating, or rendering indistinct, objects situated at a distance, differentiating, so to speak, the crisp visibility of scenes or objects at varying distances from the point of sight as if a transparent gauze screen were interposed.

It is aerial perspective which, in a large measure, enables us to judge of the distance of objects. There are some countries where the atmosphere is so clear as to enable one to see the details of scenery several miles away with a degree of clearness equalling that of two or three furlongs in other places; and, however valuable a photograph of such scenery may be from a scientific point of view, its value in an artistic sense would be greatly diminished, bearing an analogy to a portrait in which an elaborate background was represented with a degree of sharpness of detail equalling that of the principal subject.

The acknowledged beauty of photographs of English land

scape scenery is largely owing to atmospheric perspective, which, while leaving the foreground and the near distance sharp and vigorous, exercises a softening and subduing influence upon the middle and extreme distance. True, a warm current of air near the surface of the earth produces, so far as definition is concerned, the same effect, although somewhat differing in character. We were made sensibly aware of this a few days ago, when endeavouring to obtain a tele-photo view of the Alexandra Palace from a suburban village slightly over a mile distant from this edifice. The day was singularly clear and bright, and we gladly embraced the opportunity of endeavouring to secure such a view as we knew the new production of Dallmeyer gives us in perfection. To our surprise it failed to do so. But the cause speedily became apparent, when, upon examining the palace through a telescope having a power of fifty times, every stone and ornamental detail of the building seemed as if dancing. This tremor was caused by heated air currents intervening between the window from which the camera was directed and the subject. A few hours later and the air became quiescent; but this was rapidly succeeded by a density of the atmosphere so pronounced in character as to render it undesirable to repeat the photographic experiment at that time.

We mention this, as we can readily conceive of the possibility of others achieving a non-success without being aware of the cause. And, while speaking of this or any other lens of abnormally long focus, we may say that a view of any object taken at a considerable distance away cannot possibly have the same contrasts in light and shade as one of similar dimensions obtained with a lens of short focus from a near point of view. Two hats of equal blackness possess a very different photographic value, if one be placed only a few feet away while the other is removed to a distance of half a mile. While the nearer one is still black, the farther one is grey. Those who employ the tele-photo lens must, therefore, use it with becoming discrimination if the best possible results are desired.

A PHOTOGRAPHIC RECORD AND SURVEY.

The details of the work done during the past year or two by the Birmingham Photographic Society towards securing a "photographic survey" of a portion of the county of Warwickshire, and the further circumstance, as mentioned by Mr. W. Jerome Harrison in the course of his paper at the Photographic Society of Great Britain on Tuesday night, that the completion of the work must occupy some ten or twelve years more, afford us, and perhaps him, a very forcible idea of the magnitude of the undertaking concealed in his suggestion that, to say nothing of individuals, the whole of the two hundred and fifty societies of the United Kingdom should unite, under the protecting wing of the parent Society, to secure a large number of photographs of the face of creation in the British Isles for the benefit of posterity. The term "survey," in such a connexion, is clearly a misnomer, as Mr. Harrison does his best to prove by his suggestions that such pictures may be taken at random by individuals, and by photographic societies on Saturday-afternoon excursions.

The Birmingham Society has gone about the work of the local survey in a thorough if scarcely systematic way, and photography is certainly the gainer by the 1000 or more admirable views it has secured. What value posterity, or even contemporary society, will place on the work, is hard to tell. The success of the Birmingham Society appears to have induced other Societies to engage in similar work in other parts of the country, a fact of which we are glad, as it imparts to the Societies in question a definite end and aim, and a distinct *raison-d'être*. One can understand that the mass of results which the Birmingham Society is able to point to is not due either to the need or the value of the work which it has taken in hand, but rather to the spirit of enterprise and energy which pervades that excellent Society, and which is calculated to carry it through all its undertakings, of whatever nature. But we are not sure that a little local enthusiasm over the innumerable opportunities for taking pictures of ancient houses and other objects in Warwickshire is likely to be contagious in parts of the country where such natural advantages do not prevail. This, we fear, foredooms Mr. Harrison's idea to remain permanently in the suggestive stage.

While we admire Mr. Harrison's enthusiasm in the pursuit of that idea as well as feel ourselves in a complimentary mood towards him when contemplating the mass of figures and details bearing on the subject which he brought before us the other night, it would be absurd to regard the scheme of a concerted "photo-survey" by the Societies of the United Kingdom as other than impracticable, unwieldy, of doubtful utility, of problematical longevity in its execution, and of debatable practical value when (if ever) finished. The suggestion with a purely local application looks and reads well on paper. Extended to the British Isles, it would, or should, mean millions of photographs which even the Photographic Society of Great Britain with its newly found energy might hesitate to take charge of. They would require a National Gallery for storage, and a Government bureau for their administration. Conceive such a scheme really started, and divided and subdivided among the various participants in the work, it is difficult enough, in all conscience, for them to know where to begin; but where should they leave off? Where is the line to be drawn between that which is worthy of recording by means of photographs and that which is not; and, above all, who is to draw it? If the picturesque, the antiquated, and the interesting is to be preserved on paper for the historian of remote centuries, why not the unlovely and the unpicturesque, since both equally go to the making of history?

On the whole, while we commend local survey or record work, as calculated to infuse a new motive for existence into the lives of the ever-increasing photographic societies, we are not sanguine that any universal or concerted scheme stands but the remotest chances of success; and therefore, on those grounds, it is to be hoped no such scheme will take shape. As in the case of the proposed photo-technological institute, we demur to the theory that Government aid should be solicited or expected. Such a demand would inevitably meet with failure. The Government, we fear, would take up the attitude of many individuals, and say that, while it is an admirable idea to place a great many features of modern architectural beauty and topographical interest on record, there are many things in existence nowadays which are unworthy that honour, and which posterity would not thank us for preserving, and a possible permanent record of which we ourselves cannot contemplate without a shudder. In future ages, we of this epoch no doubt will be heartily laughed at for many monstrosities, including the "German cooking-stove, with the griffin on the top" of the London City Corporation in Fleet-street, our ugly public buildings and railway bridges, and

so forth. Would, indeed, that all records, photographic and otherwise, of such monstrosities might be for ever obliterated! Alas that Mr. Jerome Harrison should wish it otherwise!

Fused Silver Nitrate and Sensitiveness.—In a letter in another part of the JOURNAL, Mr. J. Barker, *apropos* of a discussion which took place at the last meeting of the London and Provincial Photographic Association, points out that, if two gelatino-bromo-iodide emulsions be made identical in every respect, except that ordinary commercial silver nitrate is used in one case and fused silver nitrate in the other, the latter emulsion will be more sensitive than the former. This is a fact which we are able to confirm, although we are unable to explain it, but we do not think it is taken advantage of in commercial plate-making.

Trade Marks Act.—This Act has certainly stimulated photo-mechanical work in this country. Before the Act was passed, some firms who professed to do photo-mechanical printing themselves actually had it executed abroad, and their own name put upon it. Now, if this were done, the prints would be liable to arrest at the Custom House, unless they bore on the imprint the intimation that they were produced abroad. The consequence is that some houses who used to get their orders executed on the Continent have either to work the processes themselves, or decline to accept the orders, except, as is sometimes the case, they get other houses here to supply the work. It is, perhaps, on the score of photo-mechanical work more than in anything else that the home photographic industry has benefited under the Trade Marks Act.

Photography and Technics.—*Apropos* of photographic surveys and records, the Brechin Society has struck out in a somewhat novel direction, that of getting together a collection of photographs, in the form of lantern slides, illustrative of the staple manufactures of these districts. This set of slides, if accompanied by an explanatory lecture, as mentioned, would prove highly interesting if loaned to other societies. What the Brechin Society is doing other societies could also do in the staple industries of those localities. There is scarcely any branch of manufacture from which not only interesting, but instructive, photographs could be obtained. Possibly this may be done, independently of photographic societies, by the proposed Technical School. In reference to this subject, one thing occurs to us: some manufacturers who have gone to great expense in perfecting their appliances may object to their being photographed, and the photographs being so widely exhibited.

Xylonite or Celluloid in Photography.—It will be remembered that some year or two ago we directed attention to xylonite as a basis for photographs in imitation of ivory, and suggested the carbon process for the purpose to those in search of novelties. Soon afterwards we were shown some prints on it produced by a photo-mechanical process, apparently from an intaglio plate, that were very fine indeed. These were produced in America. We were recently shown some on the same material, also printed in the States, but from "process blocks," that were almost equally as good. From Germany also we have seen some very good process block prints on celluloid in imitation of ivory. This compound, under its different names, is now finding many uses in connexion with photography. Why cannot it be as well used for printing upon by collotype as for intaglio plates and typographic blocks? Collotype on it would make excellent pictures as Christmas cards and the like. One of the difficulties, we believe, in printing on celluloid is that of getting the ink to dry so that it does not rub off. Ink that will dry on paper in an hour or two will not be sufficiently dry, so as not to rub off, in as many weeks. In this matter the Americans have been the most successful. Why?

Insurance Rates.—The recent conflagration at Messrs. A. & G. Taylor's calls to mind that fires in photographic establishments are far less frequent now than they used to be some years ago. At one time the insurance offices had numerous and heavy calls upon photographers' policies; but, with one or two exceptions, the cause of the fire could in no way be attributed to the inflammable materials used in the business—collodion, &c. However, the frequency of the claims some twenty years or so ago induced the insurance companies to raise their premiums very materially, the cause then assigned being the combustible materials employed. Some offices still adhere to the old rates, and many photographers are paying them. At the present time, in the majority of studios, no inflammable substances are used; therefore the risk is no greater than in any other business. Again, a claim on a photographer's policy has seldom now to be made. Why, then, should the old rates be sustained? However, some offices have reduced their rates, and we know that others have done so in individual cases when they have been protested against and the names of other offices mentioned. Insurers should bear this in mind when the next premium becomes due. By the way, Fire Insurance was one of the subjects that the National Association of Professional Photographers were to take in hand.

Cleaning Daguerreotypes.—Referring to the subject of the Daguerreotype process in our last issue, it was mentioned that this was—and for that matter is—the most permanent of all silver processes. A Daguerreotype may become so tarnished that the image is obliterated. But if the picture were gilded, as described, we have only to remove the tarnish to restore it to its original condition. This professional photographers are frequently called upon to do, and, although they succeed in cleaning the picture, they do not, in all cases, restore it to its original brilliant state. It is sometimes veiled, or has marks upon it when finished. The reason is this: after the picture has been treated with the solution of cyanide of potassium, sufficient care is not bestowed on the washing and drying. The picture, after being well washed under the tap, must be carefully washed with distilled water, and then, before the water has time to collect in tears, the flame of a spirit lamp is applied to the uppermost corner of the plate while held in a slanting position, and then gently applied to the other portions. If veiling or drying marks are to be avoided in "restoring" Daguerreotypes, *pure* water must be used for the final washing, and the drying effected without a check, as was explained last week and well known to all who have worked the Daguerreotype process.

Photography in the Colours of Nature.—On Tuesday afternoon last Mr. F. E. Ives delivered the first of two lectures on this subject, before a large and interested audience, at the Royal Institution. The following is a synopsis of the lecture: Origin of the idea of colour photography by a composite process—History of composite heliochromy—Ducos Du-Hauron's process—Cros' process—Poirée's process—Dr. Vogel's discovery of colour sensitisers—Improvements following Dr. Vogel's discovery—Dr. Albert's chromo-collotype—Dr. Stolze's original suggestions—The Young-Helmholtz theory of colour vision—Maxwell's measurements of the power of different spectrum rays to excite the respective fundamental colour sensations—Definite application of the Young-Helmholtz-Maxwell theory in composite heliochromy. On this occasion only one picture was exhibited on the screen, the subject being that of a girl with rustic surroundings. The colours of the picture were most vividly and faithfully rendered. Our readers have already been made familiar with the principles and details underlying Mr. Ives' method. The second lecture will be given on Tuesday next, May 17. In our correspondence columns this week appears a letter from Dr. H. W. Vogel in reference to some points raised by Mr. Ives in his address to the Franklin Institute last year.

COLLODION EMULSION NOTES.*

It was remarked, at the London and Provincial meeting, that I had stated that precipitated emulsions do not keep; but, so far as my recollection goes, that is scarcely accurate. Speaking entirely from memory of some years since, I found Chardon's emulsion to keep admirably, at any rate, for some months, and, if anything, to improve

* Concluded from page 294.

in clearness and quality of image. But the undeveloped image on the exposed plate had absolutely no permanence, and commenced to fade out in a very few hours, as I once found to my cost. I went away for a fortnight into North Wales, taking with me a stock of clean glass and Chardon's emulsion, coating my plates each evening in my bedroom, and developing one or two of those exposed. The negatives developed on the spot were all that could be desired, some of them as near perfect as photographic work could make them; but of several dozen exposed plates I took home with me I did not get a single good negative, except those exposed on the last two days of my holiday. The trouble was *under-exposure* apparently in every instance, but that this could not be the case was proved by one plate exposed on my first day out, and which was fortunate enough to get about three-quarters of an hour's exposure in sunshine while I was chatting with a fellow amateur who "chanced along," thinking I had closed the lens. Now, three-quarters of an hour was usually quite enough in those days even for a slow plate, but this one refused to show any detail in the distance some miles away.

The fault was unmistakably in the film itself, and arose from the presence of something which destroyed the image almost as soon as formed. It could not be excess of soluble haloid salts, because although Chardon's emulsion contained before precipitation excess of chloride of cobalt, that and all soluble matter was bound to be removed in the operation of washing, which was very thorough. And besides, had that been the cause, the plates would have been too insensitive to make a picture, even if developed at once. The real cause I set down, and I still believe correctly, to the decomposition of the precipitated pyroxyline itself, which, by liberating nitrous emanations destroyed the image. The action on the emulsion would only be to keep it clear and free from fog, and perhaps very gradually to render it thinner and more fluent. The latter, however, I never kept it long enough to try.

After all, there is no better plan of washing than the original one of pouring out into a thin layer, drying very thoroughly, or until all the solvents are gone, and then careful washing in hot water if you like. In this we adhere as closely as possible to the treatment of an individual film when treated singly; the soluble matters are thoroughly eliminated while the pyroxyline itself is sufficiently firmly set to resist any action of the water. Under such treatment alone can the retention of the original qualities of the unwashed emulsion be relied upon in the washed product. For small quantities, say, five or ten ounces, such as an amateur is likely to "tackle" at once, there need be not the slightest difficulty in any stage of the work. A twelve by ten plate formed into a dish by glueing strips of paper round the edges, when placed upon a level surface forms an admirable evaporator for half a pint of emulsion, which will be set perfectly hard in twenty-four hours or less without artificial aid. The leathery skin thus formed is torn up into small fragments and soaked for half an hour or an hour in cold water, and may then be passed through half a dozen changes of hot or even boiling water, after which there is not much danger of any bromide being left in it.

The drying is found by many to be the most difficult part of the process, hence they resort to all sorts of expedients, such as only half drying by pressure, or by soaking in alcohol. More harm and uncertainty arise from such expedients than from anything else. Apart from the fact that a half-dried pellicle sometimes refuses to dissolve at all, the introduction in this manner of water into the emulsion is chiefly instrumental in causing half the troubles we hear about in the way of streaks, mottling, and crapiness. One of the chief beauties of a washed emulsion should be its freedom from structure, due in great measure to its being made with strong solvents. Let the pellicle then be dried thoroughly until hard and crisp. If it takes a little longer to dissolve, the result is far superior. After pressing out as much of the moisture as possible by *gentle* pressure between blotting paper, lay the pellicle upon a sheet of clean paper in one of the cardboard boxes used for packing plates, and carry it to the kitchen oven, which should not be too hot. The box provides protection from light and sufficient exit for steam and moisture, and the contents can be examined in the dark room from time to time until dry.

For those who hanker after the sort of state of division given by precipitation, the following plan will answer admirably, possessing the good points of that method without its uncertainty; but it is rather troublesome, and not altogether pleasant, if you do not like ether fumes. Pour the emulsion into a *basin*, and allow it to evaporate for some hours, with occasional stirring, or until it begins to clot. Then, in the dark room, proceed to stir it vigorously with a silver fork or spatula, exposing it to the atmosphere as much as possible to draw off the solvents. If an artificial blowing arrangement is handy, so much the better. At first the mass only gets thicker and lumpier, but after a while, when all the ether is about gone, it forms almost suddenly into fine shreds, from which a clear liquor—alcohol and water with the soluble salts—separates. Continue the stirring until the solid portion clots firmly together, then pour off the liquor, press out the surplus and leave the solid emulsion spread round the sides of the basin for half an hour; then stir it into cold water, wash, pour off, and repeat a few times, and finally squeeze as dry as possible in a cloth before scattering the fine filaments over the bottom of the drying box, as already described.

This method reduces the emulsion to the very finest possible condition for washing, drying, and redissolving; but it is troublesome, except on a small scale, or on a very large one with suitable machinery and appointments.

W. B. Bolton.

THE CAMERA AND THE CONVENTION; OR, PICTURESQUE SCOTLAND AND PHOTOGRAPHY.

II.

Going round the Queen's Drive from St. Leonard's Gate there is, on the face of the hill to the left, a peculiar formation of rock, called "Sampson's Ribs;" this spot may be of interest to the photographer of a geological turn of mind. The range is of porphyritic greenstone columns, of a pentagonal or hexagonal form, from fifty to sixty feet in length, and five feet in diameter.

Craigmillar Castle.

Duddingston—this village is situated at the back of Arthur's Seat when viewing it from the city, and it will be found a most delightful place for the exposure of a few plates. The village itself is one of those old, sleepy, contented-looking places that never seem to grow, with the placid rocks at its foot, and the old church on a promontory standing high up over the loch. The whole surroundings lend themselves to the making of good pictures, and the swans on the lock give an opportunity for some good instantaneous work. From this spot Craigmillar Castle is at quite a convenient distance. This was the old castle at which the Convention group was taken by Mr. Crooke when the Glasgow meeting visited Edinburgh to spend the day with their friends there. Those who have seen Mr. Crooke's picture must feel that it is the best and most picturesque group that has ever been taken at any convention. Craigmillar Castle is well worthy of a visit, specially to those who delight in ruins of historical interest, the place being so closely associated with Mary Queen of Scots. Over the hill to the south of the Castle, there is a clachan called "Little France," where Queen Mary's stables were located when she resided at Craigmillar. This little bit composes well for a picture.

Newhaven and Portobello.

Leaving the south side, and coming down to the Forth, about two and a half miles north from Edinburgh, lies Newhaven, where is to be found the Newhaven fishwife, that toiler of the sea, whose unique dress and original appearance are known all the world over.

Newhaven is a small fishing village, composed of old houses, outside stairs, and awkward gable ends, which help so much to make a picture, the inhabitants themselves being a distinct community from all around. The men are mostly all fishermen, and the females fishwomen. The place possesses a trig little harbour, and lots of fishing-boats about usually, so that the combined materials for making good pictures of this class will be found here easier and better than at any other place along the coast.

About two miles to the east of Newhaven lies Leith, but it is of no account photographically, except the docks, perhaps, where some good shipping effects may be had; and for water pictures we have seen some successful negatives taken at the end of the pier, which runs out about a mile. With a fairly good sea on, and the ships caught making for the entrance between the piers, fine effects are got.

Keeping along the coast for about two miles, we come to Portobello, which may be termed the Brighton of Edinburgh. In the summer-time the sands here will be found quite a happy hunting-ground for the snap-shot and hand-camera operators, and there is usually a pretty large

contingent of these at the Convention meeting. Why, at one of the trips at Bath we remember, out of a gathering of some thirty or forty, the whole company had hand cameras, with the exception of three.

Three miles further on we come to Fisher Row and Musselburgh. We have got, in days gone by, some good studies at the Fisher Row end of Musselburgh. The river Esk, which runs through the town, possesses some artistic points away above the bridge, but Musselburgh, taken altogether, is not of great interest to the photographer.

Roslin Chapel and Castle.

Roslin, a hamlet about eight miles south from Edinburgh, is a charming spot for a day's outing, possessing, as it does, a chapel, a castle, and a glen, all within a small radius. The chapel is well known, and is one of the favourite resorts of all tourists to Edinburgh. It is a highly decorated specimen of Gothic architecture, and in the interior of this chapel is to be found the "Prentice's Pillar," a marvel in sculptured foliage, and about which the keeper tells the following story :—

"The master-builder of the chapel, being unable to execute the design of this pillar from the plans in his possession, proceeded to Rome, to study a similar column there. During his absence his apprentice proceeded with the execution of the design, and upon the master's return he found this finely ornamented column completed. Stung with envy at this proof of the superior ability of his apprentice, he struck him a blow with his mallet, and killed him on the spot."

The castle stands on a rock overhanging the picturesque glen of the Esk, with surroundings of foliage, and rock, and bubbling stream—the very centre of a happy hunting-ground for the camera men.

All the way to Lasswade, by the banks of the Esk, is full and rich with pictures. Hawthornden, the seat of Drummond the poet, is also on this road, and close to the glen.

About two miles from Lasswade is Dalkeith, the seat of the Duke of Buccleuch. The palace and gardens command notice both for their beauty and historical interest.

Peebles and North Berwick.

Peebles, about twenty-seven miles from Edinburgh, situated on the banks of the Tweed, is a good district, but not so condensed and easily handled as Roslin. It is surrounded by gentlemen's seats of great beauty. Nidpath—one of the old defence castles—is only a mile from the town and very romantically situated.

North Berwick, twenty-two miles from Edinburgh, on the east coast, is a small seaport and coastguard station, with surroundings that suit the seeker after picturesque scenery. The town itself is famed for its Law and Links, neither of which are of much moment from a photographic point of view. North Berwick Law is a conical hill over 600 feet high, standing out all by itself, and which can be distinctly seen from Edinburgh. The Links are held in high esteem by golf players. As a summer residence North Berwick is much in demand. To the east of the town, and keeping to the shore, lots of good rock and seascape pictures are to be had, with the Bass Rock in the distance. The Bass Rock lies out about two miles from this point. About two miles along the shore we come to Canty Bay, which is worth a plate or two, but beyond this is Tantallon Castle, a most imposing subject, towering in rugged grandeur to the sky. When the tide is out, photographing from various points is easy. Tantallon is easy of access also from the high road, and the ruins would delight many. About two miles to the west of North Berwick is Dirleton, a neat little village with beautiful gardens, where good work will be found, and Dunbar Castle is about nine miles from here.

Melrose, Abbotsford, and Dryburgh.

Melrose, Abbotsford, and Dryburgh are places of absorbing interest to all who have read Sir Walter Scott's works, and who has not? The distance from Edinburgh to Melrose is thirty-seven miles, and at Melrose the Abbey is the point of greatest interest. It has been photographed so often, in general view and in parts, that it must be familiar to all, and those who only know it by pictures and reports must have a great desire to visit it, and make pictures of it for themselves.

Abbotsford, the romantic home of Sir Walter Scott, is three miles from Melrose, the way thither being filled with places of interest. The house itself, standing on a promontory quite close to the Tweed, makes a charming picture. A wealth of both interior and exterior work is to be found here. From here we go on to the spot where Sir Walter Scott is buried—Dryburgh Abbey. This Abbey is five miles from Melrose, and there, in St. Mary's Aisle, is the last resting-place of the Wizard of the North.

To do this part of the country justice it would take a week or two; for miles around wood and water scenery abound, picturesque beyond description; and within an easy railway journey is Jedburgh Abbey and Kelso Abbey, and every mile of the way contains places of beauty and interest.

The Forth Bridge!

The Forth Bridge is an object of considerable interest to the visitor to Edinburgh, and it comes naturally within the range of one of the places that must be done; an engineering feat of such magnitude appeals to many from the mechanical point of view, but by far the greater number go to look upon it as a sight worth seeing, only that and nothing more. In driving to the Forth Bridge, about half way out we come to Cramond Bridge, under which the river Almond flows. In this vicinity some good studies are to be got.

The grounds of Dalmeny Park is the next place of note upon the way. This is the seat of the Earl of Rosebery. The last time we visited the Forth Bridge, we wanted to take some pictures in these grounds, but were not allowed to do so. We had perfect liberty to walk through them, but no liberty to photograph.

The Forth Bridge itself must be photographed: interesting, yes; but there is nothing pretty about it.

Dunfermline and St. Andrews.

Taking the train at the bridge, half an hour's journey brings us to Dunfermline, where stands an abbey of considerable historical interest. Robert the Bruce is interred here, besides many other kings and queens. The last time we were at this abbey the keeper showed us a very peculiar effect in the construction of the pillars. The carved work round them, which twines to the top, has the effect of deceiving the eye, and makes the pillars look ever so much narrower at the top than the base when viewed from a given point, and by changing your position quite the contrary effect is produced, seeming broad at the top and narrow at the base, and when coming near they are quite symmetrical. If there, you should ask to see this.

The town itself does not possess any beauty for the photographic visitor, but some of the gentlemen's seats around are historically interesting. There's Cutross Abbey, the old seat of the Bruce family, and the scene of the murder of Lady Macduff and her children, Dunemarle Castle.

St. Andrews is about an hour's journey north-east from Dunfermline, and here stands a good day's work ready for the enthusiasts, with its cathedral, its castle, and its colleges, besides other buildings of note, a romantic shore, and renowned golf rinks, a choice of work to suit the varied inclinations. St. Andrews is about forty-four miles from Edinburgh.

Around Edinburgh, within an easy distance of the city, not going beyond the "Braids" or the "Pentlands," many charming spots for photography are to be found, but we anticipate the demand will be for spots of a more pronounced nature, with a tradition, a story, and a beauty, and at a further distance from the immediate vicinity of the city. We give these in more detail.

JOTTINGS.

Not long ago I was present at a meeting of a photographic society, and the discussion turned upon the difference between ordinary nitrate of silver and the "recrystallised" salt. One member said that the only difference between the two salts was, that in the latter case the large crystals were selected from the ordinary stock, and these, *ipso facto*, became "recrystallised" silver nitrate, which was consequently sold at a higher price. In the course of a somewhat long and varied career in photography, I am enabled to state that the process of recrystallisation here indicated is the one almost generally adopted; indeed, I may say that it has been frequently my duty to carry it out practically, to the monetary confusion of a host of too-credulous purchasers, and the enrichment of my sharp-practising principals. Hence, when I see recrystallised silver mentioned in a collodion or any other formula, I smile.

That a monument to Petzval, the great mathematician, whose calculations and formulæ for photographic lenses are as valuable to-day as they were fifty years ago, is an undertaking in which all photographers and opticians might worthily join, admits of no denial. The fact that such a project is afoot is recorded in one of your contemporaries last week—but, alas! from my file of the British, I see that it was noted and commented upon in your Journal several months ago. Verily, news travels i a circle! The funniest part o

the matter is that the paper which gives this old and crusted par. as an item of "news" is never tired of publishing its refusal to print anything which has appeared in the other photographic papers. I could give you dozens of instances in illustration of this irony of fate.

Just as there are still among us adherents of the Stuart dynasty, so it seems there are those whose affection for the wet-collodion process "age cannot wither, nor custom stale." I fear, however, that the process is more talked and written of than practised, except among a very few process workers. Why even these gentlemen still adhere to it I cannot imagine, as sufficient density and clearness of line for all purposes are, as the examples I have often seen convince me, not abnormally difficult to get on gelatine plates by the exercise of a moderate amount of skill and care. But there is one thing, by the way, in which the wet plate-process possesses a distinct advantage in working over gelatine plates, which is seldom noticed in the papers and articles dealing with the subject nowadays, and that is, the extreme rapidity with which the developed negative is fixed, compared with a dry-plate negative. I was forcibly reminded of this the other day when taking some outdoor pictures for an old wet-plate worker who was waiting outside the dark room to see the results. The pictures were under-exposed, and they each also took at least a quarter of an hour to fix, a circumstance which led him into various unfavourable comparisons of the two processes, to the disadvantage of the new one. Modern gelatine plates vary much in the rapidity of solution of the unaltered salts in the fixing bath.

I have no doubt it was an amusing night at the South London Photographic Society when the President made a handsome addition to the funds of the Society by selling the new cold-bath platinum pictures he had developed in the course of his demonstration of that process; but I confess that to me the incident would have looked "better rounded off" if the Society had not profited by the transaction, and the money had been handed over, say, to the Photographers Benevolent Association. I thought that photographic societies existed for the advancement of photography, and not as money-making concerns. I see that another Society lately held an auction of members' old apparatus, and I have heard of one which has varied the monotony of its proceedings by indulging in the wild delights of a raffle. All this is very entertaining, but it is slightly indecorous, and is, I think, calculated to make the judicious grieve. At any rate, the publication of these sales by auction, and otherwise, is out of place in a Society's report, which, if primarily intended for the information of members, is also, I conceive, meant for the enlightenment of outsiders, or why do secretaries take advantage of your benevolent pages?

I was much pleased with Mr. Frederick Park's generally lucid paper on *Bromide Enlarging*, read before the Newcastle-on-Tyne Association; but I think a little more clearness on certain points would not have been amiss. For example, he says he usually takes his negatives for enlarging with stop *f*-32, but he omits to tell us the focal length of his lens, so that the information on the point is, to say the least of it, incomplete. Again, when he says that with a large stop more light strikes the centre of the plate than the edges—and consequently that density is greatest at the centre—he is, I think, making a statement which is possibly open to serious objection if it is to have a general application. May I ask him what he calls a "a large stop," and also to indicate the precise aperture to employ so as to combine the equality of illumination he desiderates with freedom from excessive central density, which he tells us occurs with a "large stop?"

I observe that, in the regulations of the exhibition of photographs and apparatus to be held next week at Bath in connexion with the Floral Art and Industrial Exhibition, "contributors will be allowed to affix name and title to their works, and, *if professional*, the price" (my italics). Now, sir, why "if professional?" Am I to understand that a poor wretch of an amateur will not be allowed to sell his pictures—in other words, may not become a professional at will? or does Mr. W. M. Ashman, in an excess of innocence, imagine that no amateur could, would, or ought to sell his pictures if opportunity arises? This a free country, and long may it remain so, even though professional photography be thereby ruined,—

> "Let laws and learning, arts and commerce die,
> But spare us still the amateur, say I."

Excuse the parody, sir. [We do, although it is a poor one.—Ed.] But the sentiment is widely entertained. Stay, perhaps Mr. Ashman contemplates starting an association for the protection of the poor professional against the avaricious amateur? Good luck to it.

Cosmos.

ON THE PRESERVATION AND DETERIORATION OF GELATINE NEGATIVES.

III.

Of the many fruitful sources of deterioration of gelatine negatives perhaps there is none more insidious than the sudden changes of temperature and accompanying humidity of atmosphere frequently met with in the early spring and late autumn months of the year. During the month of March we have had notable instances of such weather, when, with the thermometer standing at 70° in the forenoon, it has fallen suddenly, and during the night so low a reading as 5° of frost has been registered, this being again followed by rain and dampness of atmosphere, so much so that walls of staircases in the interior of houses were running down with damp. It is at such times as these, more than any other, that sad havoc is played with gelatine negatives, and, therefore, every precaution should be taken to guard all valuable negatives that may be in printing, or even stored away in places liable to contract damp.

Let any one anxious to experiment in the amount of moisture that a gelatine negative will absorb from a damp atmosphere just try the result of placing a perfectly dry film, varnished or unvarnished, after the same is carefully weighed, into a damp washing-house for forty-eight hours, and then weigh again; or, if the more simple method of holding the damp plate before a fire be adopted, he will be surprised at the amount of vapour that will be thrown off. It very frequently happens that negatives in this condition are, without any thought, dragged out from some cupboard, or other strange place of doubtful suitability, and hurriedly placed in a printing frame, just to throw off a print or two, when, should the temperature be somewhat higher, and the atmosphere in a tolerably dry state, there is no outlet for the condensed moisture which is sure to arise within the film, the result being the formation of minute spots, which in course of time play sad havoc by becoming so pronounced as to spoil the negative entirely. At the time these spots will not be visible, but if such a negative be carefully examined when in the printing frame, it is more than likely this evil will be detected. When this condensation is going on, small circles of prismatic colours may be noticed when looking down on the glass side of the negative. Sometimes they will be seen in numbers of two or three close together. When such are noticed the evil has begun, and before long, in the exact place where these tiny prismatic circles were seen, distinct spots will be found to have put in an appearance in the film. This can be easily proved by carefully marking the place where these prismatic circles are seen.

When such spots are examined with the aid of a microscope—using, say, an inch power—they will be found to present totally different appearances according to the manner in which they are viewed. When examined on the film side, they will show no colour circles; but when they are looked at on the glass side of the negative, they are found to present one of the most beautiful objects any one can view under a microscope. The spots will be seen to be caused by perfect circles of varying tints, and in nearly every case the exact centre will show the fine granular deposit of metallic silver undisturbed, but around which the most perfect circles of varying colours and widths will be seen to have formed deep down in the film, as it were, against the glass, and these circles, it seems, go on increasing as the spots get larger. For a long time I was puzzled to account for these prismatic circles, but I have clearly traced them to the condensation of moisture in the gelatine film, caused by bringing a negative in a damp condition into a heated atmosphere without any precautions being taken to gently assimilate such to the existing temperature. All valuable negatives that have been stored away ought to be gently warmed before being put into a printing frame to print.

Another insidious source of damage to gelatine films will be found in the common practice of placing a number of negatives in a packet film side to glass side, or, in other words, film side all turned inwards, without any thought being given to the contaminations which the glass side of a negative may have contracted from dirty fingers or other injurious sources. This is very likely to happen when

frames are hurriedly emptied and the negatives placed away on end, as described.

Intimately associated with the deterioration of negatives is the question of their proper storage, and perhaps there is no better method to adopt than that followed in large establishments, where they are placed away in racks with a constant current of dry air passing through them. Of course, to the great army of amateurs such precautions are not to be thought of, and the more common practice of placing the negatives in paper envelopes is adopted; but such is by no means a safe practice to follow, for when such are stored away in a damp cupboard or other unsuitable place this form of protection is just about the worst possible. Far better is the plan of employing grooved boxes, and when such boxes are placed in a dry situation the risk is reduced to a minimum; but it is always wise to gently assimilate the negative to the existing temperature before placing same in the printing frame.

Luckily we are not left in much doubt as to when a varnished or unvarnished film has contracted damp from the atmosphere. Should the precaution that I have referred to not have been taken, but, on the other hand, the printing paper be merely placed in contact with the damp film, it will not be long before the paper will begin to show signs of puckering up by the absorption of the damp from the gelatine, which causes it to expand just as if a damp sponge were drawn across a dry sheet of printing paper. When such takes place there is great danger of deterioration in the future. T. N. Armstrong.

SOME CONDITIONS INFLUENCING THE WELFARE OF PHOTOGRAPHIC SOCIETIES.

[Brixton and Clapham Camera Club.]

In thanking you for the honour of having elected me a Vice-President of this Club, compliance is necessary with the request of your Hon. Secretary, that an address shall be delivered to you this evening in place of a paper by any of the members. To a person of few words the fulfilment of such a duty is not always easy; so, after placing before you a few ideas as to some conditions influencing the welfare of photographic organizations, the remainder of this evening will be spent in viewing a display upon the screen, by Mr. Levitt, of the lantern pictures taken by Mr. Leon Warnerke, of Government and other photographic establishments in Continental Europe. Mr. Warnerke has left England for St. Petersburg, so is unable to be present here to-night.

A photographic organization may be prosperous in its intellectual capacity, or it may be prosperous in its funds and the number of its members; it may also be prosperous in both. When it is but materially rich, a local society may go quietly and comfortably on its way, and be little esteemed outside the limits of its own parish; when, however, its intellectual powers add considerably to the progress of photographic art and science, its discoveries attract the attention of the world.

That a local society should raise itself above the dead level of the general run of such organizations, it is necessary that each individual member, when time and opportunities permit, should take up some special work, and afterwards place the results before the whole body of the members. In reading the records of the average proceedings of local photographic societies, one would suppose that none but silver and a few other processes existed, and that we have nothing to talk about at our meetings but the working of common processes connected with the plates, films, and papers ordinarily sold in commerce. What is wanted is, that one member shall say, "I will carry on novel photographic researches with the salts of iron;" that another shall resolve to do the same with uranium salts; that others shall experiment with the salts of nickel, cobalt, and other metals; that one member shall take up the primuline process, and discover its possibilities, and so on, so as to get away from the more common processes, and to discover new things about the others. We should also have men quitting the beaten track in matters artistic; the finest artistic effects in photographic printing are, I think, produced by Klic's—better known as the "photogravure"—process; yet, where is the amateur who works the same? Dr. Emerson announced his intention of beginning to work at it, but I have not yet heard of the results.

I do not believe in appointing committees to conduct such investigations from a pious sense of duty and a mere belief that the work ought to be done. It is for the individual to strike out new paths, not as a task but as a pleasure. It is for each of our younger members to resolve to no longer live as a nonentity, but to do something to increase the store of human knowledge, and to stand out as a benefactor of the race.

What dreary reading is to be found in the local society reports in the photographic press! We are, perhaps, informed therein that Mr. Jones sat down amid loud applause, after reading a valuable paper—in which the reporter can find nothing worth printing. Sometimes we are told how J. Smith, Esq., J.P.—a man knowing nothing of photography—honoured the Photographic Society of Little Pedlington with his presence, and how all the members grovelled before him. I think that the editors of all the photographic papers will thank me for speaking of the lack of general interest and of useful information in the average reports of the local societies. They cannot well leave the reports out, because their circulation might then fall in the various localities. Let, then, some of the energetic young men connected with this club bring in some results of original research, and make the reports of our proceedings worth reading. The club has the advantage of possessing as president a physician of high attainments, who can appreciate the value of original research by the members, and who himself does not much follow beaten tracks in photography; a president who does not feel satisfied unless he can set up his camera in the crater of an active volcano, such as Hecla, is sure to encourage all those members who begin to strike out new paths of experimental investigation.

One of the largest and most prosperous local photographic societies in the kingdom is the Manchester Amateur Photographic Association, and I was told at one of its meetings, by one of its most active members, that lantern displays and lectures, to which the public were admitted for a trifling fee, had great influence in bringing in new members and increasing its popularity. Close at hand we have a busy centre of traffic and commerce, and, if next winter we advertised lantern entertainments for the display of instantaneous photographs of scenes near Brixton Station, they would probably "draw," as, apart from other considerations, so many persons would be curious as to whether they or their houses had been pictured.

A good library furnishes an inducement to join a photographic society. The Camera Club has a good library, and the Photographic Club a moderately good one; those of all the other photographic societies of London are, so far as I know, poor in the extreme. Perhaps we shall be long before possessing a good library, but the central free library is now being built close by the spot on which we are now assembled. It might be well if this Club memorialised the authorities thereof to the effect that the collections of chemical and photographic books they have already placed in the branch libraries are so poor as to be beneath contempt, and that they may as well possess one decent collection of scientific works and books of reference, so that people shall not be obliged to journey hence to the British Museum or the Patent Office Libraries because of the literary poverty of our own locality.

A good hon. secretary is essential to the welfare of every photographic society; he is to the society what the lens is to the camera; he is the official means of communication with the outside world; and, if he be intellectually dim, woeful will be the results to the organization he represents. He has to do all the hard work, and is forgotten while everything goes on well; when things begin to go wrongly, he has to bear all the abuse. When you smite him on the one cheek, he has to turn to you the other also; and, when the money balance of the society is on the wrong side, he has to cheerfully make up the deficiency out of his own pocket. We cannot too much honour such laborious and long-suffering individuals. I think that it is the duty of the wealthier members of the photographic community in London to "dine" all the photographic hon. secretaries once a month. Had Mr. Louis M. Biden adopted this plan before he attempted to federate all the London photographic societies in hot haste, he might have been more successful in carrying out his plans. One stands appalled at the magnitude of the knowledge of the public aspects of photography in London, which would be concentrated at a dinner party of the secretaries of the various organizations.

Exhibitions, summer outings, and other incidents of existence have their influence on the welfare of photographic organizations; but enough has been said upon this subject for one evening, and we will now give attention to Mr. Warnerke's lantern slides.

W. H. Harrison.

THE WET COLLODION PROCESS.

[London and Provincial Photographic Association.]

In response to the request of our Secretary to "tell us something about the wet-plate process," I have embodied a few jottings from my note-book in the form of a short paper, in the hope that they may be found useful to those of our members who may be desirous of working the wet-plate process. This is comparatively an easy affair now, seeing the facilities that present workers have for obtaining any article required, which is a very different state of affairs from that which prevailed in

olden times, and, as each of the materials used had a decided effect upon the other, the difficulties of the old worker were often great, it being absolutely necessary, if first-class work was required, that suitable samples, which would work together, should be obtained. For instance, if the alcohol was weak, it would not dissolve some samples of cotton, and the addition of an extra quantity of ether, to compensate for the weakness of the alcohol, did not mend matters much, as, although it would then, perhaps, dissolve enough cotton, the resultant film was usually crapy, porous, and rotten; acid ether would also liberate iodine, and rapidly disorganize the collodion, and, unless the pyroxyline was suitable for the purpose intended, first-class results were hopeless.

It was also necessary to suit the iodiser to the cotton, or *vice versâ*, as a sample of cotton that was almost useless with cadmium could be made to give a passable result with ammonium and sodium, though many little dodges could—and, in fact, had to be—resorted to, such as adding a trace of carbonate of soda or ammonia when the pyroxyline was tough and horny, and the addition of a few drops of tincture of iodine if the collodion was too new, and that general panacea for wet-plate woes, the addition of a little more acid to the bath.

I will pass round a few specimens of old positives and negatives, calling your attention specially to the positives, which, although taken many years since, still retain the characteristics for which this process was noted, and which, I submit, have never been excelled, and will conclude with a few formulæ that I have found to work well in my own practice.

FOR RAPID WORK.

Bath.

Fused nitrate of silver	50 grains.
Rain or distilled water	1 ounce.

Should be quite neutral, or faintly acid with acetic acid.

Collodion.

Alcohol, ·805	½ ounce.
Ether, ·725	½ ,,
Iodide of potassium	3 grains.
Iodide of Cadmium	3 ,,
Bromide of potassium	1 grain.
Bromide of cadmium	2 grains.
Pyroxyline	7 grains.

Developers.

No. 1.

Protosulphate of iron	30 grains.
Formic acid	10 ,,
Glacial acetic acid	½ drachm.
Alcohol	1 ,,
Rain, or distilled water	1 ounce.

No. 2.

Protosulphate of iron	240 grains.
Acetate of copper	10 ,,
Glacial acetic acid	3½ drachms.
Alcohol	3½ ,,
Rain, or distilled water	8 ounces.

Intensifier.

Pyrogallic acid	4 grains.
Citric acid	12 ,,
Rain, or distilled water	1 ounce.

Add a few drops of silver from nitrate bath as required.

Fixing.

No. 1.

Cyanide of potassium	¼ ounce.
Water	10 ounces.

No. 2.

Hyposulphite of soda	1 ounce.
Water	5 ounces.

FOR ORDINARY WORK.

Collodion.

Alcohol, ·805	½ ounce.
Ether, ·725	½ ,,
Iodide of cadmium	2 grains.
Iodide of ammonium	3 ,,
Bromide of Cadmium	½ grain.
Bromide of ammonium	1 ,,

Bath.

Nitrate of silver	35 grains.
Rain or distilled water	1 ounce.

Add nitric acid until blue litmus paper turns red.

DEVELOPERS.

Negative.

Protosulphate of iron	½ ounce.
Glacial acetic acid	½ ,,
Alcohol	½ ,,
Water	8 ounces.

Positive.

Protosulphate of iron	¾ ounce.
Nitrate of baryta	½ ,,
Nitric acid	20 minims.
Alcohol	½ ounce.
Water	8 ounces.

Powder baryta and dissolve, then add the iron powdered; mix and let stand for about ten minutes, then filter out precipitate, and add nitric acid and alcohol.

Transparencies.

Protosulphate of iron	8 grains.
Or, pyrogallic acid	2 ,,
Glacial acetic acid	20 minims.
Citric acid	2 grains.
Water	1 ounce.

If tone too blue, decrease citric acid and increase acetic, or *vice versâ*.

J. BARKER.

CHRONO-PHOTOGRAPHY OF STAR TRANSITS.

FOR some time past I have had under consideration as a leisure subject the application of photography to the taking and timing of a star in transit across the meridian, and, as I fancy I can now see my way through the problem, I will endeavour to give an idea how it is to be done. To properly present it would require several sheets of careful drawings, which, had I the time to prepare them, would scarcely be of sufficient general interest to warrant the expense of producing blocks, or to induce the Editor to give the space for their appearance. Any description, therefore, must be of the nature of a sketch, which I hope to make sufficiently clear to enable a draughtsman accustomed to clockwork to produce the designs for an intelligent mechanic to work from.

Briefly put, the apparatus consists in the following:—

1. A small roll-holder with spool of sensitive paper, and sparking arrangement for the field of the telescope.
2. A similar one for the recording apparatus, which consists of three thin steel skeleton dials for indicating, respectively, seconds, minutes, and the hour, driven by the standard or other controlled clock, and moving between the sensitised paper and a sparking arrangement.
3. An ordinary clock with suitable gearing for driving the two roll-holders.
4. A source of electricity for producing the sparks.
5. A lever to actuate a clutch for imparting motion to the roll-driving gear, and to operate the switch that completes the electrical circuit.
6. "Contacts" on the clock pendulum for closing the sparking circuits to produce the spark in front of the two roll-holders.

Such are the main features, which I will now endeavour to describe in greater detail, and will commence with the fitting of the telescope. As in most cases it will be desirable to retain the instrument in a condition for eye observations, it will be necessary to open its tube at the side in the neighbourhood of the field or principal focus of the objective, and fit it with a grooved frame in which can slide another frame or carrier bearing the usual arrangement of cross wires in juxtaposition to a screen of metal having vertical slits, the centre or principal one being prolonged to the lower part of the plate, or on to a separate one if necessary. By pushing this frame from side to side either the cross wires or the slits may be adjusted in the field of the telescope for use at will. At the eyepiece side of the metal screen, in grooves or other mode of fastening, the small roll-holder carrying the slip of gelatino-bromide paper is secured, and at the foot of it on the other side, and opposite to the extended slit, a small receptacle for the sparking arrangement is affixed. The driving spindle of the roll-holder, being provided with a spur wheel on one end when in position, is made to gear into a similar one on a spindle having bearings on the sliding carrier, and extending outwards sufficiently to enable a light pulley on its end to be chain-driven from a loose pulley running on the end of the pivot of the telescope, where a second loose one in communication with the driving clock imparts motion to it by means of a clutch.

To give an idea of the principle of the recording apparatus, it will be well to imagine a clock fitted with centre seconds, minute, and hour hands. These being removed, fix upon their respective spindles,

in place of them, three light metal discs or wheels, varying to the extent of the band of metal forming the periphery in size. The rim of the outer, or larger one, is pierced with seconds, one to sixty—or half-seconds, by repeating each number in pairs, marking the second one of the pair with a dot, to distinguish it from the first—the rim of the next wheel with minutes, one to sixty: and that of the third, and smaller one, with the hours, one to twenty-four. A convenient point of these circles must be chosen for putting the fixings to the clock-case to carry the roll-holder and sparking box, between which the discs must have perfect freedom to revolve, the fine figuring on the discs being opposite to the narrow opening in the roll-holder in front of the sensitive band on the one hand, and to the opening in the sparking box, for the passage through the figures on the discs to the sensitive surface, of the light emitted by the spark on the other. The driving spindle of this roll-holder is geared up to the same clock which is driving the other one, the speed of both being alike. As the recording discs are driven continuously by the standard clock, accurate time to half a second, or less, is always shown at the above openings.

I need say but little respecting the source of electricity. Any of the methods of producing a small spark of just sufficient brilliancy to impress the sensitive surface will suffice, the apparatus for the purpose, I believe, being part of the outfit of most observatories.

A lever within reach from the eyepiece, constructed to actuate the clutch that throws the driving connexions of both roll-holders in and out of gear, also closes or opens the main breaks in the electrical circuits, whose complete closing and sparking depends on the pendulum of the standard clock, whose "contacts" must be placed to ensure its taking place instantly and exactly at the second or half-second, whichever circumstances may require.

Enough, perhaps, has been said in description for the present, it being extremely difficult to know when to stop. To go thoroughly into the mechanical details and necessities of each item is scarcely possible without working drawings and most tiring repetitions, and, as these would be out of place here, I will cease and leave it open for any one really interested in the matter to write to me privately at Littlehampton for any further enlightenment. It is necessarily a subject of interest to but a limited number only, the photographing and timing of stars in transit across the meridian being too expensive a luxury for private persons to indulge in. A few words in explanation of the working of such an installation will, however, not be out of place, and may possibly tend to clear up any point that is not quite plain in the preceding.

With this appliance *in situ*, the preparation for the transit of a particular star in respect of pointing the instrument and fixing it in position, would be made in the usual way. A few seconds before the computed time of passage, the lever would be shifted to connect up the rollers of the slides with the driving clock, and close the main breaks of the electrical circuits, immediately upon which the sensitive bands commence to move, the one behind the fine slots of the metal screen in the field of the telescope, the other behind the opening of the slide before which the numbered rims of the recording dials, that, through having been kept continuously in motion, show true time at that spot. At the same instant the standard clock, by means of its pendulum contacts, commences the sparking in the two circuits, and at each impulse passes one through the arrangement at the telescope, to impress itself on the sensitised surface travelling before the extended slit; and another from the front, through the small group of numbers on the recording dials to the sensitised paper in motion behind, this being repeated every time the pendulum makes a contact. The passage of the star across the slits will impress its image on the upper part of the band. A few seconds after the computed time, a touch of the lever suffices to stop both the rolling of the paper and the sparking, when a re-adjustment of the telescope may be done, and another star timed in like manner.

When the two bands of paper are cut from the rolls and developed, the one at every spark will show the hour, minute, and second in small dark figures; the other, at similar intervals, the same number of vertical lines, and above them the four or five dark short lines produced by the star as it passed over the slits. Should these appear, say, over the fifth vertical line, the fifth group of figures on the other band will give the true time of the transit to any degree of accuracy, the machine being unaffected by "personal equation." JOHN HARMER.

THE PRESENT POSITION OF PHOTOGRAPHY IN RELATION TO BOOK AND PERIODICAL ILLUSTRATION.*

Washed Drawings.

Now, although by any of these methods charming work can be produced, the negative taken will vary very much in each system. It is telling you, gentlemen, that which you already know, that, of the seven colours forming the solar spectrum, the blue ray, or actinic ray, is the only ray that works in photography, and that, as the tones approach nearest to the blue colour, so do they act with greater rapidity upon the sensitive plate, the blue sky being pure white in the finished print, while the red cow is black—both exposed the same time. This is just what takes place in the photographed drawing; as the white is more or less mixed with the washes, so it partakes of a blueish tint, the result being that the wash photographs lighter than the tone of the drawing, the parts where the white is not have a brown faded cast, the result being that the tint comes darker. I hope I make myself clear. This hastening or slowing of the different washes of the drawing, as they incline to blue (through the admixture of white) or to brown is going on all over in every little particular, the result being that the relative values of the tones in the finished photograph on wood are often wrong all over, and it is only by the engraver consulting his original every few minutes that he can pull it together at all.

Now, here is the danger of the tone photographic process; let the drawing be ever so suitable, this danger is always present. But no two artists draw alike, and, as a rule, no artist will draw long in one style, and I think you will follow me when I say that the object of the artist when he begins his drawing is to produce a good picture. He cannot be bound by any hard-and-fast lines without suffering from the restraint, and, although one artist's work may be more suitable for the purposes of a photographic process than another, there is a good amount of accident about it. Not only does this apply to tone drawings, but in pen-and-ink drawings also there is the greatest difference in handling of one artist against another; one will draw with a firm point and cross hatch at right angles, another has a timid, scratching style and a knack of cross hatching at very acute angles. The resulting block in the first place is a clear printing one, and in the other simply a block all over ink traps. Process men well know this, and get into disgrace with publishers, at times being blamed for want of skill, when the real fact is that they are powerless against a drawing that is unsuitable.

Another point comes in here. One advantage claimed for these drawings on paper was that the artist could draw much larger, and refinement by reduction would take place; like many things in this world, this sounds well, but how are the facts? Well, I will tell you how it works, both financially and in the resulting block; first of all, financially. Publishers have a knack of judging the value of the drawing by the size they produce it; and you can well imagine the feeling of disgust a photographer would have who had taken a 15 × 12 negative, and, this being approved by the customer, he is told, we will take half a dozen C.D.V.s. Now, the resulting picture, provided the drawing is a rough one, will improve by reduction; but, if the drawing is a satisfactory one, the small reproduction will, in many cases, have too much in it for printing purposes. My own practice is to draw a trifle larger, the slight reduction refining the work. As in engraving, I advocate the use of a magnifying-glass for the engraver, as the engraving appears on an enlarged scale, and the finished picture is reduced as seen by the naked eye.

Day's Process.

I have gone into these matters at some length, as it is upon these and the power of any process to meet all these difficulties that the ultimate success or failure depends; and, that you shall clearly grasp my reasons for the opinions I form of the way photography has grasped the difficulties, or failed to grasp them, and what, in my opinion, is its position to-day, and, clearly understand me, I purposely avoid touching the many interesting experiments made by photographers to produce surface blocks for typographical printing. I say nothing of the gelatine plate, made to swell up and then made a printing block by having small flints pressed into it; nor will I go into the latest company I have seen announced, where the zinc plate is put on one side, and the negative becomes the mould for the electrotyper. I have no shares in it, I am glad to say; but I do not like to spoil the amusement of any man. However, I cannot pass a process that is used by many papers. It is now some years ago since I saw it shown up at the Society of Arts, and worked a bit with it myself. It was then known as Day's process, and this is how it is used: A number of sheets of gelatine are pressed, some with lines, and some with dots. The roller of ink is rolled over the pattern chosen, and under this is placed the outline drawing on Bristol board. Of course, the design can be seen through the gelatine, which is ink-side down on the drawing. Now the operator presses down with a burnisher the parts he wishes transferred, the ink marking the Bristol board, and the deed is done; the pen-and-ink sketch becomes henceforth a mongrel affair, part pen-and-ink, and part engine-turned dots. I confess this is very painful

* Concluded from page 309.

to me, but it is a cheap way to produce an appearance of finish, and so is used pretty freely.

The Sketch and the Camera.

With the exception of engraving on wood by machinery (of which more hereafter), I think all processes for the production of pictures (we need deal with) for book and periodical illustrations are before you, and now let me see how the position stands to-day in relation to these things. I speak to you to-night as an artist and engraver, but I claim also to be an enthusiastic and successful photographer. I seldom stir out for a holiday without a sketch-book and a snap camera. When I found process causing a panic among engravers I turned my attention to photography, and instead of an enemy I found a true friend—a helper to me in many ways. I therefore speak without bias. I admire talent, no matter where it comes from; it is a beautiful brotherhood—the brotherhood of art—that no sea can divide, no distance keep asunder, no time efface. Although the hands are dust that laid the brush to the canvases in our national museums the art lives, and we worship the memory of those who produced it. It is this true love of art that cannot be kept back for long from a people yearly growing into higher tastes and knowledge that makes me doubt the possibility of any mechanical process satisfying them, and ever superseding the hand and brain of those who have made a life-study of art matters. I think the battle has been a good one, and in some respects photography has scored points and will hold them against all opposition. I feel sure, however, it will have to show much more pliability before it can supersede the woodcut from the highest to the lowest style of illustrated periodical. That there is a market for it we have proof, but only as padding to high-class periodicals. The struggling, sickly army of periodicals catch at it as a dying man at a straw; it is process or nothing for them, and pictures they must have, and process ones, at the very lowest possible price.

Where Photography has Scored.

I say that there are points where photography has scored, and, in many respects, routed the army of facsimile engravers, both in quality and price, although I cannot agree with the article in *Pick-me-Up* of a few weeks ago, that it has killed them quite. It has made them think, and, instead of being mere machines, they have learned to use the brains that are a great deal more plentiful in this world than some suppose if people will only shake off sloth and indulgence a little, and endeavour to think. You have heard me say here that photography has acted as a blue pill and black draught to art, and process has acted in the same way to engravers; but we are quite alive and kicking, I can assure you. I consider, when a good drawing in line has to be engraved, the photographic engraving process will render it with great beauty. I have some things by Abbey, printed in *Harper's Magazine*, that have much of the charm, and much of the sharpness, of etching. I do not, however, suppose for one moment that they were produced cheaply; but to produce the same thing by wood-engraving would require a talented man, and would take immense time, and this applies in all pen-and-ink work. Provided the artists who make the designs are talented men, and they are well printed on good paper, they leave nothing to desire; although the popular taste is not in favour of this style of work, and "never will be," they tolerate it if well done here and there, and in comic papers it is accepted, but they cannot be educated to believe that a man's coat can be satisfactorily expressed by cross lines.

The Tone Process behind the Woodcut.

The photographic tone process is, at the present time, far behind the woodcut in artistic merit. No matter how the process is varied, the same quality runs throughout the entire picture. Sky, middle distance, and foreground are rendered with the particular stipple or line alike; in one direction giving a tame and insipid result, so different from the engraved block where the hand of the engraver has translated the design with one quality and direction of line for the sky, the middle distance so fine, perhaps, that the line can scarcely be seen, while the foreground is made up of bold, vigorous touches, helping the aerial perspective and expressing the texture of any substance, any material; be it stone or silk, the process block expresses each with the same line upon the soft, sweet face of a young lady dressed in the choicest robes and the dirty old beggar in rags she is giving alms to. This want of quality of line is very dreadful to the educated taste, but I cannot see how it can be otherwise. Another trouble with the tone-process block is the lack of printing quality in it. It is true printers are surprised at what they get out of them, but they have to be very careful, keeping them very sparsely supplied with ink, and, as a result, getting prints lacking contrast, no true blacks, no true whites, all flat and grey. Publishers are shown by process men copies printed upon clay-faced paper, and jump to the conclusion that results ought to come as good as the specimens in their own publications; they do not stop to think that but a few copies only are printed, with the greatest care and with special ink. But it is a very different matter when large numbers have to be run off upon poor paper, with everything cut to the lowest price; so, until the tone process will stand the treatment a wood block will stand, it must perforce be greatly against it. You will at once see where the wood block and process differ. The engraver cuts in the deepest parts a line deep enough to ensure printing; as he approaches the lighter parts, he increases the depth of his cut, and in the whites he cuts deep holes, so that the ink-roller cannot possibly get at the wood. But in the process all are eaten away to the same depth, although engravers are employed to deepen the white parts and dodge up other imperfections; they are known by the dignified name of pickers. This is very noticeable where process blocks are used for advertisements in periodicals, as these pages on which advertisements appear have little care bestowed upon the pictures printed. Even the safest woodcut comes out very poorly; therefore the drawings, even in line, for these pages should be of a very elementary character, while the tone process is no good at all with poor printing, and this must be expected in the advertisement sheets of most papers.

Engraving by Machinery.

I spoke of engraving by machinery. Well, this is a most useful invention. The tool is held by a machine and so is the wood block, but every line is watched and varied by a competent engraver; and, although the main masses are cut by the machine, it has all to be gone over by the hand of the engraver to finish up, and also to cut all small details. It is principally used in cutting machinery, and the beauty and accuracy of every line directed by the brain of the engraver gives a result that I do not think anything can beat, while for printing purposes it is simply splendid, the cut being so firm and true.

I have gone into this matter at some considerable length to-night, and to the best of my ability I have placed all processes for the production of pictures for our books and periodicals before you, and now I have only to run over the ground quickly and close my lecture. Well, then, the present position of photographic process is that line photographic process in good hands from capable drawings is most useful, cheap, and faithful. As regards the tone process, although it is used very extensively, it is very unsatisfactory all round; it is three times the price or more than the line process; it is tame and uninteresting, unsafe in printing, and in no sense can it compare even to cheap engraving; it is an apology for a picture, possessing very little artistic merit; it is unsuited for high-class work, and also just as unsuitable for cheap periodicals, given anything like long numbers. No, something much better must come to the front before the tone drawing for our periodicals can be taken from the engraver, and I am at the present time reproducing a number of things that were done by process and are thrown aside as not suitable; the machine engraving shuts the door upon it for all mechanical work, and, but for the band of starveling publications that live upon advertisements and trade puffs, it would have but few customers. What its future may be it is impossible to say; but of this I am sure, that the principle is wrong, to render everything with one line or stipple, which must produce tame and inartistic work, and in these days of higher education in art matters, even if the technical difficulties of cheap printing with poor paper and ink, running long numbers, can be overcome, popular taste will be felt by the editor who stands at the helm of his periodical, and that taste will demand in any photographic process the same artistic rendering of subjects that the old engraving is capable of.

Tom Symmons.

THE "ANSCHUTZ" INSTANTANEOUS CAMERA.

Our readers will remember that some months ago we drew attention to a remarkable series of animal and other studies by Herr Anschütz, which were on view in this country for a few weeks, and we have now had an opportunity of inspecting the camera—or, at least, what we are assured is an exact *facsimile* of it—by which those pictures were taken. The "Anschütz" camera has a solid body, and is fitted with a five-inch rectilinear lens, by Goerz, with rack and pinion adjustment for focussing. The focussing screen occupies the usual position, but the necessity of employing a focussing cloth is obviated by an opaque, collapsible hood being fixed on the screen-frame, which renders the screen sufficiently dark for focussing by. The shutter, which is of the curtain type, works immediately in front of the plate, and its rapidity is controlled by separating its halves vertically—the largest opening allowing of an exposure calculated to be one-seventy-fifth of a second, the diminution of the opening down to one-sixteenth of a second, reducing, it is said, the exposure to one-thousand two-hundredths of a second. The shutter is wound, and set by a milled-head screw at the side of the camera, and is released by touching

another in front. The finder consists of a square frame, equally divided into four, placed on the front of the camera, and when the object is axial to the centre of the cross wires, and a small upright on

the back of the camera, it occupies the central portion of the picture. Solid double backs are supplied with the camera, which may be employed on a stand as an ordinary camera, and, with the special head supplied placed in a number of positions. The Anschütz appears a very serviceable and workmanlike instrument for moving objects. It is in the hands of the Blackfriars Photographic Company, of Surrey Row, S.E.

Our Editorial Table.

"Photographic Work" is the title of a new weekly contemporary issued by Messrs. Piper & Carter, so long connected with the *Photographic News*. The latest claimant for public favour is both well edited and well printed, and, according to the address to its readers, is intended for "the busy man."

Photographic Notes and Formulæ.

By Sir David Salomons, Bart., M.A., F.R.A.S., &c.

This brochure (published by Marion & Co.) consists mainly of papers and articles written by the author at various times. Among the topics treated are "Large Heads in the Studio" (for which a lens having a focus over thirty inches is recommended), "Rules for Exposure," "Relative Rapidity: Ratio and Standards," "The Distance beyond which all will be in Focus," "Enlarging and Reducing Tables and Exposures," "Depth of Focus," &c. These and other topics are most lucidly dealt with, although their proper appreciation will require mathematical knowledge.

The Perfect Light Filter.

By Hunter & Co., Herne Hill, S.E.

Messrs. Hunter & Co. have sent us a sample of a specially stained paper which transmits a considerable amount of light that is reasonably safe either for the dark-room window or the lamp-shade. We entertain a high opinion of it.

We have received the catalogue of Messrs. S. B. Hardcastle & Co., of East-street, Brighton, which, for size and completeness, vies with the lists of many London houses. The catalogue of Mr. George Kemp, of Chester, has also reached us. It is concise and neat.

Climax Plates.

A package of dry plates, "the Climax," received from John J. Griffin & Sons, Garrick-street, W.C., has been tried by us and found excellent. Their sensitometer number is 22.

Glanzfarben für Photographische Retouche.

Hinton & Co., Bedford-street, Strand. [illegible]

Now that so much printing is done upon highly glazed paper such as the aristotype, a suitable medium for spotting prints, and one which would preserve the glazed surface, was much needed. This is now being supplied by Messrs. Hinton & Co. in the form of little collapsible tubes of colour with screwed tops, a set of seven of which, fitted in a neat pocket case, supplies the requirement for spotting in every shade, from white to the darkest tone obtainable, passing through every intermediate gradation. Each tube bears on it an appropriate colour band, showing exactly the nature of the pigment it contains. This set must prove a great convenience to all who desire to send out spotless prints.

Developing Dishes for Yachting.

Messrs. Hinton & Co. have also introduced a set of developing and fixing dishes of a novel and useful character. The edges are turned over, lapping inwards, in such a way as to prevent the spilling of the fluid contents, even when moved about or held with the extreme of unsteadiness, as in a yacht on a much-troubled sea. The special adaptation of each dish is imprinted on the ends or side of each in bold black letters, which are sunk in the material. This is a novelty in dishes, and one which will commend itself to all.

Mr. W. J. Dibdin, of Sutton, Surrey, has sent us a very neat and conveniently arranged automatic card exposure table, which shows at a glance the exposures to be given under different conditions of light and stops. It is both handy and convenient.

PHOTOGRAPHIC SOCIETY OF GREAT BRITAIN.

May 10.—Mr. T. Sebastian Davis, F.C.S. (Vice-President), in the chair.

Mr. Harold Sands was elected a member.

During the evening the Chairman welcomed Mr. F. E. Ives, of Philadelphia who was present, to the meeting of the Society.

The Exhibition and the Convention.

It was announced that the following gentlemen had been chosen as Judges for the next Exhibition of the Society:—Messrs. F. P. Cembrano, jun., W. E. Debenham, W. England, F. Hollyer, and J. Traill Taylor, and, as scientific experts, Captain Abney and Mr. Andrew Pringle.

The following gentlemen were nominated as delegates of the Society to the forthcoming Photographic Convention of the United Kingdom at Edinburgh in July next:—The President (Captain Abney), Messrs. W. Bedford, N. Cowan A. Mackie, L. J. Montefiore, A. Pringle, J. Traill Taylor, and L. Warnerke.

A Proposed Photographic Record and Survey.

Mr. W. Jerome Harrison read a paper on *A Photographic Record and Survey*, in which, after mentioning that a topographical survey of the United Kingdom had its origin in the conflicts with the Highlanders, he traced the history of the various Ordnance Survey maps which had been prepared during the century, and referred to the photographic work done at the Survey Office at Southampton, and by Colonel Waterhouse in the Government Survey of India. In the records of the Hydrographic Survey there was no reference to photography being employed; but in the German Navy it was employed to make rapid surveys of coast lines. The Geological Survey was based on the work of the Ordnance Survey, and photography was not employed. The United States employed skilled manipulation largely for the same kind of work. The Committee of the British Association, appointed in 1889, had secured 588 photographs of geological interest. The same Association had also appointed a Committee to collect photographs of clouds, &c., of which 153 had been obtained. In the survey of the heavens more progress had been made than in that of the earth, as, thanks to Messrs. Henry, they had a better idea of the visible parts of the moon than of the Polar regions or Central Africa. The desirability of a photographic survey was obvious. The historian, the man of science, and the artist would give a great deal for photographs taken at the close of each century for the last 2000 years. Briton, Roman, Norman, and Saxon history would have been brought down to us. Change in the appearance of things was rapid; churches were being restored, old houses swept away, dress becoming uniformly ugly, and manners and customs changing. Photography should supply a record of the present state of things for posterity. The survey would be best carried out by professional photographers—individuals, Societies, and the Government. In 1888 he suggested the appointment of State photographers, and the idea was endorsed by Captain Abney. As had been recently gathered from Dr. Jeserich's paper, a photographer attached to each police division would be useful in criminal cases. In the case of the recent Whitechapel murders he might have photographed certain inscriptions on the walls, attributed to the murderer, before they were obliterated. Having pointed out the part which individuals, Government, and Societies might take in the work, Mr. Harrison said he estimated the 251 British Societies included in the Almanac to have a membership of 20,000, and the total number of photographers, amateur and professional, in Great Britain to be 250,000, and then proceeded to give a history of the Warwickshire Survey, founded by the Birmingham Photographic Society, the work being undertaken in sections, with the six-inch Ordnance Map as a basis. Exhibitions were held in 1890 and 1892, at which there were classes for Survey pictures. Referring to the later work of the Survey Council, he said the size of picture recommended was whole-plate, and the pictures had to be printed by a permanent process, and mounted on mounts provided with all details as to subject and the focal length of the lens on the back. A special exhibition opened in Birmingham on Monday next, at which 1000 prints, the majority whole-plate size, were to be exhibited. In future there would be annual exhibitions, and possibly a quarterly journal and portfolio would be issued. The section for the Birmingham Society for 1893 comprised Stratford-on-Avon and the Forest of Arden. The Birkenhead, North Staffordshire, Cardiff, Manchester Amateur, Wolverhampton, Barnstaple, Chester, and Exeter Amateur Societies were doing survey work. In conclusion, Mr. Harrison remarked that the parent Society was subject to long periods of lethargy, from one of which it had recently recovered. It ought to be a Royal and chartered Society. He commended the matter of the survey to the Affiliation Committee.

Mr. T. Bolas drew attention to a work on Photogrammetry, by Commandant Legros; also an article in the *Correspondenz*, dealing with photogrammetry; and Mr. W. E. Debenham said that photogrammetry was thoroughly worked out in Germany. Several recent publications had detailed instruments and methods for enabling surveys—but not of a picturesque character—to be made.

Mr. F. Ince objected to the term Photo-survey, as used by Mr. Harrison, which did not convey the idea the lecturer gave. He imagined some description would be given of the way in which surveying would be done by photography. The system of taking such pictures as were on the walls in many parts of the country was, no doubt, useful for enabling us to keep records of the kaleidoscope changes of the time, but they were in the nature of a record, and not of a survey.

Mr. G. L. Addenbrooke thought that the exact places from which pictures were taken should be carefully recorded, and the focal length of the lens given, so that dimensions could be calculated. In that way it would be possible to ascertain the extent of the subsidence of buildings, as well as the growth of trees, the general aspect of the country, and the course of streams, the photographs enabling them to form an estimate of the action of time; but this could only be done carefully, and under scientific directions, and hardly in the way Mr. Harrison suggested—by photographic excursions, which were not in the nature of a survey. The pictures shown resembled the work done by the Society for Photographing Old Buildings in London. If a workable scheme were made on a more limited and humble scale, perhaps the Society might carry it out in conjunction with the affiliated Societies.

Further remarks having been made by Messrs. Bolas, Debenham, and Clifton,

The Chairman drew attention to a large number of photographs of geological subjects taken many years ago by Mr. Cole, a member of the Society, which were now on view at the School of Mines, in Jermyn-street. The prints appeared to be not only permanent, but to convey a most interesting impression of the objects photographed. He suggested the application of Mr. Harrison's idea to the photographing of rock sections, which could be shown in the lantern. Mr. Harrison had said that we were more fortunate in our knowledge of the heavenly bodies than of the earth; but, in the case of the moon, our knowledge of it only extended to a few degrees in each direction, and it must be many years before we knew anything of the other portion away from us. The Chairman concluded by suggesting the application of photography for providing a record of the changes which the fauna of the country were undergoing.

Mr. P. Everett said Mr. Harrison had given a most extensive programme, with which the Affiliation Committee was not at all in a position to deal. The matter would involve a large amount of work and organization, and the necessary funds were not at their disposal. He liked to look at the thing practically, and he had serious misgivings as to the utility of a survey conducted on the lines indicated. Topographically or geographically, he doubted if the pictures shown would be of any great service at any future time. No system seemed to have been pursued in their production. They did not seem to have been taken on any definite plan or with any definite end. For a permanent record some system should be adopted. As to Mr. Harrison's suggestion, that at some future time the matter should be taken up by Government, they heard that said of everything; but no reason had ever been shown why the Government should take up this scheme. He (Mr. Everett) regarded the scheme as very immature and requiring considerable elaboration.

Mr. Harrison, in the course of his reply, pointed out, in answer to Mr. Addenbrooke, that the pictures shown had the focal length of the lens with which they were taken included with the other particulars. As to Mr. Ince's objection to the term survey, he (Mr. Harrison) said the word record had been coupled with it. The possibilities of the subject were infinite. He thought a workable scheme might be formulated, with the Society at the head of it. The pictures shown that night were only a sample of about 1100.

A vote of thanks was passed to Mr. Harrison, and the meeting terminated.

LONDON AND PROVINCIAL PHOTOGRAPHIC ASSOCIATION.

May 5.—Mr. B. Foulks-Winks in the chair.

Mr. W. E. Ward was elected a member of the Association.

Mr. R. P. Drage (the Hon. Secretary) said some doubt had been expressed at the previous meeting as to whether the blacks of the new cold-bath platinum process dried as well as in the hot-bath process. He had dried some prints, and thought the blacks were as good.

The New Concentric Lens.

Mr. J. A. Sinclair, in reference to the new concentric lens, said that some very wonderful statements had been made about it in the photographic papers, from which he thought, at first, they ought to take a discount. However, he had tried one of the lenses, and had brought it with him, together with some negatives taken with it. It was of five inches focus, and therefore suitable for a quarter-plate; but he had made his exposures on half-plates, with the full aperture, *f*-16, although originally the makers indicated *f*-22 as the largest aperture. With that stop (*f*-16) he had got good definition over the whole of the plate. He had also employed the back combination only, with *f*-32, on a whole plate, focussing the centre of the picture, and the results were very good. They would observe that the picture did not seem to be quite rectilinear on the whole plate, but possibly the hoarding in the picture was not straight. It was not quite straight in the half-plate. He showed another whole-plate, from which they would see that the definition up to the edge of the circle, with *f*-22, was very good. He had produced results with the lens which he had never expected to get with any lens. He thought the thinness of the lens made it more rapid than others of equal foci and aperture.

Mr. J. Traill Taylor also handed round a similar lens of eighth inches focus for examination.

Mr. W. E. Debenham had seen one of the lenses. He agreed that it was a great advance, and that it was a very valuable lens indeed; but he disagreed with the statement that the concentric lens, being thinner than a symmetrical, acted more quickly. The difference between the loss of light with the portable symmetrical was absolutely inappreciable. There was a certain loss of light in passing a number of surfaces, but there were the same number of surfaces in the concentric as in the portable. Would Mr. Sinclair say how much the lens was displaced to get the edge of the circle on the plate?

Mr. Sinclair could not say. With a five-inch he could get the edge of the circle on a whole-plate; but with a plate eight and a half inches square the whole of the circle could be got.

Mr. P. Everett said it had been claimed that the lens did not vignette the edge of the circle, but in the example before them the circle had a distinct vignette.

Mr. Sinclair said that at the time he was making the exposures the sun was shining in the lens.

Mr. H. Snowden Ward exhibited a book of studies, arranged by Mr. Hetherington, a New York background painter, the accessories being built up of canvas and other materials, portrait studies by various photographers being included. The studies gave hints and suggestions of what could be done or avoided. As regards the arrangements of the surroundings, he thought everybody would give a great deal of praise to the man who had got up the book. Mr. Ward also exhibited a colour screen for orthochromatic work, made by Mr. Carbutt, of Philadelphia, for which he claimed advantages over tinted and optically worked glass. It consisted of two thin glasses, with a film of stained gelatine mounted between them. Mr. Carbutt produced any tint wished for. A third exhibit shown by Mr. Ward was a camera level, by Mr. A. H. Baird, of Edinburgh. This consisted of a small plumb-bob, for attaching to the side of the camera back.

Mr. J. S. Teape had continued his experiments with the dark-room medium introduced by Mr. Bridge at a previous meeting. Exposing behind various thicknesses of red and yellow fabrics, and one thickness of the new medium, to four inches of magnesium, it was difficult to find where the light had penetrated the one thickness. With six inches the impression through it was very faint. An image was seen through two thicknesses of golden fabric, and that image was certainly stronger than the image given by one thickness.

of the new medium. It had been conclusively shown by this that one thickness of the new medium was better than two thicknesses of golden fabric. He had examined the new medium spectroscopically in the sun, and could not see a trace of blue in it.

Mr. J. BARKER read a short paper on *The Wet-collodion Process* [see p. 311].

COLLODION POSITIVES.

Mr. TAYLOR exhibited some collodion positives, which, while deficient in artistic merit, were made about forty years ago, and drew attention to the purity of the whites, to get which, he said, it was necessary to give moderately brief exposure. For a developer he had employed the usual iron solution, of about twelve to fifteen grains per ounce, with two drops of nitric acid. The great secret in getting pure whites was in the fixing. An old sample of cyanide should be continually poured on and off the picture. There was a species of electric deposition produced, under which the silver image was intensely whitened. A little bisulphide of carbon in the bath also deposited the silver in a sheeny form, which often imparted a beautiful charm to the collodion positive. Another method was that of Scott Archer: this was to dissolve bichloride of mercury in hydrochloric acid and nitric acid, alcohol, and water added. Poured on the plate, its first action was to dissolve away part of the image, but when the mercury asserted itself the image acquired great piquancy.

Mr. TEAPE said that, in making collodion positives, he had aimed to get toned pictures, as he noticed they were generally preferred. He thought whiteness gave harshness, and a tone greater richness. In the specimens shown the toned pictures seemed to have a flatness of image.

The CHAIRMAN said this was due to the weak light by which they were examining them. They would look excellent by daylight. For flesh tints he thought Mr. Taylor's pictures too white.

WET COLLODION.

Mr. EVERETT asked Mr. Barker how the rapid formula he gave would compare in rapidity with Ilford ordinary plates.

Mr. BARKER said that would depend upon the quality of the light. There would, he thought, be very little difference; in fact, he thought it would be quite equal. On a dull day in November the collodion would not be so rapid.

Mr. DEBENHAM said one of Mr. Barker's negatives was a confirmation of his (Mr. Debenham's) observation, which was not generally recognised, namely, that old collodion negatives became much more intense by keeping. Several of his old negatives would not yield decent prints now. Superior people pitied those who made such negatives. He thought this intensifying effect should be made known, in order that people should not form a wrong impression of old collodion negatives. The negatives had been intensified after fixing, and possibly some trace of pyro and silver had affected the colour of the image since. As to the formula given, he did not know how Mr. Barker got one grain of bromide of potassium into the ounce. He (Mr. Debenham) had brought a collodion and a gelatine enlargement, to illustrate the difference between them, the former showing greater clearness and purity in the blacks.

Mr. BARKER pointed out, in reference to Mr. Debenham's remark as to the quantity of bromides and iodides in the formula given, that a fifty-grain bath was recommended, which prevented bursting out in the film. He had even put three or four more grains per ounce in the collodion, and had used a bath 100 and 120 grains strong. An unsuitable sample of pyroxyline would not make a collodion at all.

The CHAIRMAN said that, with regard to Mr. Barker's remarks as to the strength of the bath, he was quite correct, and he agreed with Mr. Teape as to what he had said of the tones of the collodion positives. Mr. Barker's positives, if seen in the daylight, would be quite strong enough. Mr. Taylor's positives were lacking in detail, and the shadows were black. He had used Mr. Taylor's developer himself, and found it a good one.

Mr. DEBENHAM said that, in the bath he had recommended at a previous meeting, recrystallised silver was not necessary.

Mr. BARKER said there was an enormous increase in the sensitiveness of a bath made by fused silver, as against recrystallised.

The meeting then terminated.

North London Photographic Society.—May 3, Mr. J. Traill Taylor in the chair.—The evening was occupied as a special Lantern Night, to which ladies were invited, and attended in almost as large number as the members. The various slides were shown by Mr. R. J. Grover, and the series consisted of the set of Indian and Colonial slides now being circulated by the Photographic Society of Great Britain under the affiliation rules, followed by selections of slides contributed by Messrs. Grover, Rev. E. Healey, Douglas, Groundwater, Spiller, and Walker, and a number of slides of the Terraces in New Zealand, lent by Mr. Oakley. The slides gave great satisfaction, and a vote of thanks was passed to Mr. Grover and to the Secretary, who had acted as spokesman. The next meeting will be on March 17, and will be a Technical Meeting, at which the question of *Films* versus *Glass Plates* will be discussed. Visitors are invited.

North Middlesex Photographic Society.—May 9.—The last Lantern Exhibition of the season was held. Messrs. Barnard, Beadle, Gill, Gregory, Johnson, Jones, Mummery, Pinukett, Taylor, Treadway, and Wall exhibited slides. The selections shown were remarkably good, great improvement being noted in the work of some who had recently begun the study of the art. A selection of Indian and Colonial slides, loaned by the Affiliation Committee of the Photographic Society of Great Britain, proved most interesting. The next meeting will be held on Monday, the 23rd inst., when Mr. J. C. S. Mummery will demonstrate the working of gelatino-chloride paper, various brands and processes. Visitors will be welcome.

People's Palace Photographic Club.—May 6, Mr. W. K. Walker in the chair.—Members' open night. Mr. KENDALL asked, if a print occupied ten minutes in printing, how long would it take if a piece of ordinary, clean sheet glass were placed over the frame? In reply, it was stated that ordinary sheet glass stopped, roughly, about ten per cent. of light. The time would, therefore, be about eleven minutes. Prints from members' negatives taken at the Good Friday outing were passed round for mutual criticism. Mr. Noble' photographs of some quaint corners of Maidstone were deservedly admired. Some stereographic pictures, mounted in optical contact with glass, were on view. This was considered a great improvement on the older method of mounting on card, as the prints were preserved from scratches, and had greater brilliancy.

Holborn Camera Club.—May 6, Mr. Fred. Brocas in the chair.—Mr. A. HORSLEY HINTON read a paper on *Motive and Method*. Before taking up the paper Mr. Hinton took the opportunity of expressing his high appreciation of the honour the Club had done him in desiring him to take the presidential chair, and, whilst thanking the members, he asked them to admit him also as a working member. With regard to the paper itself, in selecting the subject, it had been his intention to endeavour, not so much to teach, as to offer some practical suggestions. His own photographic endeavours had but one end in view, namely, the furtherance of photography as an art, or at least the ascertainment of its artistic capabilities. He did not assert that photography was an art, for he had not fully convinced himself that such a statement was, as yet, justified by what they knew of its artistic possibilities. Not without hope, however, had he set himself the task of ascertainiug, for himself at least, what position amongst monochrome graphic arts photography might yet command. In photography he found he cared little for the chemical and optical phenomena with which one is brought into contact; they were to him as the mere tools and materials of the artist, with which they had nothing to do beyond acquiring sufficient knowledge of their peculiarities to enable them to use the chemicals intelligently. He would ask them to deliberately and clearly separate the scientific interest from the artistic, making up their minds which it was that appealed most strongly to them, which it was that caused them to feel such an interest in the improvement of their photographic work, or that which awakened their admiration for the work of others, and guided them in selecting their favourite pictures on the Exhibition walls, and sent them home full of great resolves for future exercise. Whichever branch of photographic work they chose, let them keep to that branch, whether it be scientific, artistic, or recreative. He wanted to draw the line firmly and definitely. From the earliest time, when the possibility of employing photography as a means of artistic expression was first perceived, men of disciplined scientific men had passed judgment upon those artistic aspirations of their colleagues which they were utterly incapable of understanding. Misunderstanding and failing to appreciate the artist's aim, they had involuntarily extolled or condemned those things which best seemed to exemplify the technicalities of their craft. So, men of different temperament, of opposite tastes and purposes, had, because brought together under the one title of photographers, been disputing and disquieting each other until now, each failing to understand that his object and pursuit might have nothing to do with that of his fellow. The sooner they recognised the wide distinction, and yet admitted that there was room for both, the better would they be able to follow out their own course, and each section of photographic endeavour, specialised in its proper channel, would the quicker meet with the recognition which it deserved. His intention in thus insisting upon the separation of the scientific from the artistic was because, in their services in the one or the other, they betrayed their initial *motive*. He then went on to compare the works of painters with photographs. Put the painter's representation of a landscape side by side with a photograph of the same, both being identical in every particular, and an unprejudiced observer would admit that, apart from colour, there was an undefined quality in the painter's rendering of the scene which the photograph wholly lacked. This quality appeared to be independent of the physical constituents of the scene, and it was therefore suggested that it was the expression of the ideal which the artist himself contributed. Presuming they were agreed that they were safe in emulating—he would not say imitating—the aim of the painter, they must accept the same as their motive, and he further ventured to suggest that it was just that higher and more intelligent motive which elevated one's work to something higher artistically. Every photographer should pause before a landscape in nature, and view it, it might be, with half-closed eyes, or any way so that they could prevent their attention being carried away by individual objects, and, pausing, see if they could find some expression behind it all—some one or more of all the glad sentiments of a bright spring morning, or the gloom and solemnity of a winter's storm. Let their motive for picture-making be that the scene, apart from the interest and prettiness attached to particular objects, conveys a sentiment, a feeling, an idea which seemed to them worthy of retaining. A brief reference to *method* closed Mr. Hinton's remarks, touching mainly upon printing, which, in his opinion, was the salvation of photography. A short discussion followed.

Brixton and Clapham Camera Club.—May 3, Dr. J. Reynolds (President) in the chair.—A paper on *Some Conditions Influencing the Welfare of Photographic Societies* [see page 311] was given by Mr. W. H. HARRISON, the new Vice-President of the Club. At the conclusion of the paper a number of slides taken by Mr. Leon Warnerke (who was, unfortunately, absent), to illustrate his paper on *Continental Photographic Institutes*, were described by Mr. Harrison, the Club lantern being used for showing them. The question box was opened, and some discussion took place upon the new platinotype paper.

Birmingham Photographic Society.—The first excursion of the season took place on Saturday, May 7. Thirty-five members and friends assembled at New Street Station and took train to Marsden Green. From thence, under the leadership of Mr. E. Howard Jacques, the party proceeded by way of Olcott Wood, Chelmsley Wood, and the River Cole, to Coleshill, where tea was provided. The walk was greatly enjoyed, the weather being charming. Upwards of 150 plates were exposed. The Council offers a prize (an enlargement) for the best picture taken on each of the Society's excursions. A hearty vote of thanks was unanimously accorded to Mr. Jacques for the trouble he had taken to make the outing a success.

Lewes Photographic Society.—May 3.—A paper was read by a member of the Society on *Retouching and the Artistic Improvement of Landscape Negatives*. The paper, which was practically demonstrated, proved most interesting, and was voted one of the most practical that has been read before the Society. At the close some stereoscopic views by Messrs. Underwood & Underwood were shown and much admired by those present.

Rotherham Photographic Society.—May 3, Dr. Baldwin (President) in the chair.—*Hand Cameras and Hand Camera Work* was discussed, a short paper on the subject being given by Hon. Secretary. It was contended that something more than mere records could be obtained by an intelligent use of the hand instrument, proof being forthcoming in the work of Mr. Dresser and others that picture-making came within its scope.

Sheffield Photographic Society.—May 3, Mr. B. J. Taylor in the chair.—The President gave a demonstration of the new Ilford printing-out paper, which called forth a discussion. It was generally acknowledged by the members present to be superior to ordinary albumenised paper.

Tyneside Camera Club.—The first excursion of the summer session was on Saturday, the 7th inst., to the ancient city of Durham. Very little time was spent on the railway journey, as express train was used each way. There was some difficulty at first by the railway company refusing to carry a Photographic Club at pleasure-party rates; but, after some "red-tape business" was gone through, they granted the pleasure-party rate. The North Eastern Railway Company state that it is the first application they have had from a Photographic Club. At Durham, the castle, the cathedral, river, and other objects of interest, of which the place abounds, had numerous plates exposed on them. When the Club kept in a body the large array of cameras—all sizes, shapes, and colours—on several occasions attracted a large crowd of curious and inquisitive persons, chiefly miners "on strike."

Edinburgh Photographic Society.—May 4, the President (Mr. H. L. Blanc, A.R.S.A., in the chair.—Mr. JAMES PATRICK read a paper on *The Imitative and Imaginative Side of Photographic Art.* In treating the subject he pointed out that photographic art was not to be considered, nor yet judged, of, as a rival to its elder sister in representative art, painting, but neither was it to be looked upon as a handmaiden to it, although it had done much for the painter in such matters as correct representation of details. He also pointed out that imitative work was not, and should not be, the chief aim of photography, but that, by proper means, it was possible to produce the higher class of imaginative art. No one would ever be able to give a poetic conception or treatment of any subject if his only aim was imitation. As showing how photography had influenced the work of the painter, he instanced cloud forms, moving water, and many other aspects of nature, for the truthful representation of which they were indebted to it. As a rule, painters were very severe in their criticisms of photography, some, indeed, denying it the faintest claim to be an art, calling it a mere mechanical handicraft; this rash statement, he maintained, was not true. Had not the photographer to deal with and represent the same subjects as many of the painters had, certainly not of those in whom the art of design and the higher imagination was developed, but they were the few compared to the many? The photographer who, by any means, expressed sentiment and showed feeling in his work, was an artist in the true sense of the word. The great difficulty he had to contend with in the exercise of his art was due to the colour difficulty; he had to depend entirely on simple light and shade in producing his representations of external nature. No doubt, the power given by many of the photographic printing processes enabled more artistic work to be produced, but the principal thing to be studied was light and shade, in order to get the true pictorial effect. This was not always attained, as some appeared to think, by having the light coming from behind or from either side of the camera. Some of the best works he had seen were taken with the sunlight in front of the lens. This mode of lighting gave a breadth and suggestiveness altogether unattainable when the usual orthodox lighting was employed, and in support of this view Mr. H. P. Robinson's *Wayside Gossip* was referred to as one example among many. Mr. Patrick, in speaking of the Impressionistic school, had no hesitation in saying that, however Dr. Emerson may have repudiated it, his work was bound to have a refining influence on "Photography as a Fine Art." If his works had done nothing else, they at least showed that breadth of light and shade, rather than excessive sharpness of focus, was the backbone of all true Art. So long as the desired effect was obtained, it was of no consequence how the picture was produced, nor with what instruments or other accessories. To be at all successful as an artist, every photographer must first be conscious of the limitation of his means for producing effect, and, when aware of the bounds within which he could work, he would be prepared to study his subject from various points of view and with the prospects of ultimate success. For many subjects, as, for instance, the view of a glen with mist on the hills, he advocated two or three negatives, using combination printing as the proper and best means of giving a true rendering by photography of what is actually seen in nature. This, he showed, was true artistic selection, and raised what was too often regarded as a purely mechanical process to the dignity of selective and imaginative art. The second ramble for the season will take place on June 4, to the grounds of Mr. Munro-Fergusson, M.P., at Raith, Kirkcaldy, at ten minutes past two p.m., from Waverley Station, and the third and last ramble will be held on the afternoon of Saturday, June 25, to East Linton, leaving Waverley Station at fifty minutes past one p.m., and for both specially reduced fares have been arranged, Raith being 1*s.* 6*d.*, and East Linton 2*s.* 6*d.*

Dundee and East of Scotland Photographic Society.—May 5, Mr. J. D. Cox, President, in the chair.—It was arranged that the first outdoor excursion should be held at Kilicrankie and Pitlochrie on the day observed as the Queen's Birthday. Specimen prints on Jacoby's collodion paper were exhibited by Mr. O. Scholzig. The prints were from negatives varying in density from thin to dense, but the resulting tone in each was identical. Although this paper does not print quite so fast as some of the gelatine emulsion papers, it tones quicker and very evenly. A French lens, with Iris shutter and the Perpetual shutter adapted for working in front of the lens, were exhibited by Messrs. Lawdon and Feathers respectively. The following office-bearers were elected for the ensuing session. *President:* Mr. J. D. Cox.—*Vice-Presidents:* Messrs. G. G. Maclaren, and William Salmond.—*Council:* Messrs. W. Baxter, P. Feathers, D. Ireland, Dr. McGillivray, J. W. Munro, A. Stewart, J. R. Stewart, J. R. Wilson, W. Bertie, W. F. Hill, Dr. Tulloch, and H. Valentine.—*Secretary and Treasurer:* Mr. V. C. Baird, Broughty Ferry. Prizes were awarded in the "Landscape with Figure" Competition to, 1st, V. C. Baird; 2nd, W. Bertie; and, 3rd, J. Rogers.

Correspondence.

☞ *Correspondents should never write on both sides of the paper.*

PHOTOGRAPHY IN NATURAL COLOURS.

To the EDITOR.

SIR,—In your JOURNAL, May 6, p. 295, you reproduce a report of the lecture Mr. Ives has given with Mr. Jennings in Philadelphia, with the coloured lantern slides of the first-named gentleman. Mr. Jennings says of his co-labourer: "When about thirteen years ago Mr. Ives undertook to reproduce by means of photography the colours of nature, he fully realised that no light task was before him." I do not object that Mr. Jennings should praise his "co-labourer" a little high before an American audience—that is only patriotic. But as Mr. Ives is now in Europe, I would advise him not to forget European work done before him in the same direction. Mr. Ives published his experiments in the so-called "isochromatic photography" in 1889, that is, six years after my investigations, and he employed no new process, but Becquerel's chlorophyll, used by the French *savant* four years ago for proving the correctness of my theory of "optical sensitisers."

I call attention here to Mr. Ives' own words in your JOURNAL, 1891, p. 104: "In 1873 Dr. H. W. Vogel discovered that bromide of silver can be made sensitive to the less refrangible rays of the spectrum by treatment with certain dyes, &c." Further on he quotes Mr. Bothamley's remarks in the *Journal of the Society of Chemical Industry*, 1887: "In 1873 Dr. H. W. Vogel discovered that if certain dyes, such as coraline or aniline green, are added to a sensitive dry collodion film, the film becomes sensitive to yellow." I think that this testimonial will be sufficient to show whether the assertion of Mr. Jennings about his "co-labourer," Mr. Ives, that the latter "fully realised that no light task was before him" is right or not.

That the principle of reproducing natural colours by combining the so-called three principal colours is a very old one (it was published in England and Austria simultaneously in 1865, and improved by Cros and Ducos du Hauron) Mr. Ives has acknowledged in his paper (*Journal of the Franklin Institute*, January, 1891).

I allow Mr. Ives the priority of having employed first those old principles for projecting lantern slides, but if he calls the attention to a new (?) printing process for pictures in "natural colours" he forgets wholly that I already gave, in 1885 in my handbook of colour-sensitive photography (*Die Photographie farbiger Gegenstände*, Berlin: Oppenheim, 1885, page 136) a new principle for printing in natural colours after Ducos du Hauron, but avoiding his failures with the so-called "complementary colours." My principle is, in short, that each of the three or more negatives taken for photographic purposes must be printed with the same dye I employ as optical sensitiser for the same plate. Mr. Ives has read this article but not understood it all, for the description he gives of my process in the *Journal of the Franklin Institute*, January issue, 1891, is totally wrong. He says I used *pigment* prints with colours *complementary* to the light. I mentioned that I rejected all theories founded on "complementary" light, for I have proved that any colour has not one, but several complimentary colours;* and, therefore, I rejected also in my printing process "complementary" dyes, and use only those which are employed as optical sensitisers, or, if these dyes will not keep, I take another one, which is spectroscopically absolutely similar to the optical sensitiser. Proofs of such prints were exhibited in the German Exhibition in South Kensington last year, and obtained the first prize. In the meantime, a company for working out this printing process in natural colours, published by me five years before Mr. Ives' patent of 1890, has worked this process in reproducing masterpieces of our most celebrated artists, such as Knaus, Menzel, &c., who never have given their works to chromo-lithographers for reproduction, and who were highly satisfied by the results of the Company mentioned.—I am, yours, &c.,

Berlin, May 9, 1892. DR. H. W. VOGEL.

DEPTH OF FOCUS: THE CONCENTRIC LENS.

To the EDITOR.

SIR,—Having been engaged some years ago in making improvements in photographic lenses, I take an interest in the above subject. The work consisted in a battle to obtain with a short focus the utmost sharpness of definition in the oblique pencils at the margin of the picture, combined with a flat field. The difficulty was so great that success was not achieved until a glass was specially manufactured for the purpose, the combination constituting an achromatic of two densities of flint, in place of the crown and flint then commonly known. This glass caused a peculiar refraction on the oblique pencils, by which they became elongated, and so produced a flatter and more extended field than had hitherto been obtained, associated with what is called "depth of focus."

In reference to the term "depth of focus" a great deal of misapprehension exists. Some say that this is an anomaly, meaning nothing else than an optical imperfection in an achromatic combination, which,

* *Berichte der Phys. Kalischen Gesellschaft*, Berlin, January, 1890.

to be perfect, should, as alleged, only give a distinct image in *one* plane. Others say that correct depth of focus is a myth, and has no existence in reality. There may be some truth in this assertion where, as in the compound microscope and telescope, the focal image from the object glass is taken up and magnified by an eyepiece of short focus and considerable power. But in the lenses used in the ordinary photographic camera no secondary magnification of an object occurs, but a reduced image is obtained on the screen itself; and depth of focus may exist to an appreciable degree, so that objects within twenty yards of the camera and distant ones may be equally well defined.

For a plain illustration, I may refer to the effect of a "pinhole stop" adapted to the camera, in place of a lens. This aperture is so small as to approximate to the effect of a single ray from each part of an object comprised in the view. As there is no optical focus, near and distant objects are all equally distinct to the utmost margin of the picture; but, of course, the small amount of light passing through an aperture of necessarily minute diameter renders the "pinhole stop" camera practically useless, even with the most sensitive tissues that can be employed; and further, as the "pinhole stop" cannot be so small as to include a single parallel ray only, but admits exterior or divergent ones, there is consequently a duplication of the image, which causes a blurred appearance in the picture.

Now, if we place a positive lens of very long focus behind the stop—say, the longest spectacle glass used (preferably of the meniscus or "periscopic" form)—the divergent beam of light from the "pinhole stop" will be brought nearer to a state of parallelism, and the depth of focus will still be approximately infinite. This condition will allow us to open out the stop, and so obtain a greater amount of light; but, to continue this operation progressively by such means with lenses of decreasing radius, we then get into all the difficulties of optical convergence, and are restricted by a real focus, at which point only definition can be obtained. The field or picture is no longer in a flat plane, but rounded, and the oblique pencils or margins of the picture are nowhere or obliterated. I give this illustration because, in the conditions of perfectly flat field, with equal definition to the very extreme that light can pass, and in what is known as depth of focus, the new "concentric lens" has all the properties of the "pinhole stop," but so perfectly are the rays combined that the full diameter may be utilised without loss of definition, thus giving an enormous increase of light in comparison. I felt so far interested in these lenses as to pay a visit to the optical works of Messrs. Ross & Co., at Clapham, and fully tested the lenses in question, and I was surprised by a degree of perfection in definition that I had never anticipated in photographic lenses.

The invention of this lens is due to Dr. Hugo Schroeder, who combines the rare qualification of intimate workshop, practical knowledge in optical matters with such high mathematical attainments in the same branch as to place him in the first rank as an optical mathematician; his manners are unassuming, and he is always willing and courteous in explaining his ideas. I recollect the first lens that he designed on the concentric principle. In the list of the Abbé Schott glass, then just issued, Dr. Schroeder noticed two examples of glass that if combined would give a result hitherto unattainable in a combination photographic lens.

After verifying the refraction, and dispersion, and optical properties by means of the very beautiful and accurate instruments of the firm of Ross & Co., Dr. Schroeder at once proceeded to calculate the formula with regard to the focus for central and oblique actinic rays in the entire combination, and so confident was he in the result that he said "it must come right." And so it turned out to be, not a single radius of curvature requiring to be altered.

The lens is appropriately called the "concentric" because the outside surfaces are so; but the singular peculiarity is that the inner surfaces of the lens, or those that face each other, are of shorter radius than the outer ones, so that any one, at first taking up the lens without looking through it, would say that it was a periscopic *negative*, and therefore could not give a focus of convergence or have any magnifying power, as the elements seem reversed. It is this peculiar form which portrays such a magnificent flat field, combined with the depth of focus, which I have illustrated by example of the "pinhole stop" experiment. This lens has been necessarily shelved for a few years, awaiting the certainty of getting the peculiar glass in quantity not to be obtained, and also to test its permanence in atmospheric conditions.—I am, yours, &c.,

May 9th, 1892. F. H. WENHAM.

THE CONCENTRIC LENS.

To the EDITOR.

SIR,—I note in THE BRITISH JOURNAL OF PHOTOGRAPHY the result of the trials of the new concentric lens being that "the new lens, with an aperture of *f*·20, covered an area of large angular magnitude—over 60° on the base line and about 80° on the diagonal—with great sharpness." I have been using the concentric for some days, and find that the stop *f*·16 gives such uniform sharpness as I have never been able to get with any other form of lens with any aperture, and that, except for objects in the *near* foreground, there is no advantage in stopping down to a smaller aperture than that of *f*·16. I have, indeed, sent back the tube of my lens to have it opened out to possible *f*·10, in hope that, if that will not answer for the practical landscape work, something between that and *f*·16 will be found as sharp as the ordinary printing of albumenised paper will require, and that the *f*·10 will give me a diffusion of focus for portraits in the open air which will satisfy the desire for a uniform "softness" of definition, which seems to be the *desideratum* with people whose ideal is the purely artistic, *i.e.*, the resemblance to the work of painting. At any rate, with *f*·16, I have such detail all over the plate as the printer cannot render for me, and with a lens of 6-inch focus on a plate 18 × 24 centimetres (9½ × 7 inches), the circle of illumination and definition goes beyond the longest dimension of the plate, so that I could cut an oval picture 9½ × 7 inches out of the print, sharp throughout, the diameter of the circle of illumination being 10 inches. This comes close on 90°, the Zeiss formula and manufacture, which we have from Berlin, giving 105° and a flat field, though the definition may be less perfect than with the Ross lens. The Roman amateurs generally are more taken with the Zeiss rapid anastigmatic, which, working with an aperture of *f*·7½, is adapted for instantaneous work, which is the *desideratum* here at present.

The favourite testing subject at our Club is the view from our terrace, giving, at the distance of about a mile, the Antonine Column, covered with delicate bas-reliefs, as all the world knows, with architectural details in the foreground in deep shadow, while the sky is crossed by innumerable telegraph wires in various directions. The use of a magnifier will show on the negative the details of the reliefs on the column, which cannot be distinguished with the naked eye, and the telegraph wires, whether they run perpendicularly across the field or diagonally, are as sharp at the edges of the plate as in the centre. The chief difficulty I have found with the lens is that of finding the absolute focus, it being difficult to adjust it within an eighth of an inch, so deep seems the focus.

The concentric lens is for pure landscape workers—a boon such as I could not have, *à priori*, believed possible, and I am still puzzled to understand how the new lens, worked at its largest aperture, can give so nearly equal illumination of the entire field. The use of the smallest stop only slightly enlarges the field and makes the line of demarcation more decisive; but the difference is very slight, though it is the only one by which I can invariably tell whether I have used the stop of *f*·16 or that of *f*·64, the loss of definition in the foreground in the former case being only noticeable when the objects are very near, say twenty or thirty feet. I have several times made negatives with the largest and smallest stops, and been unable to distinguish afterwards which was which. So I think your trials of the lens will give you something brighter than can be got with *f*·20.—I am, yours, &c., W. J. STILLMAN.

Rome, May 8, 1892.

[While we are entirely at one with Mr. Stillman regarding the desirability of having the largest aperture, even with a lower degree of definition, we still find that, with our concentric (which is two inches longer in focus than that of Mr. Stillman), the definition with *f*·20, or, more correctly, *f*·10, is better than that obtained with *f*·16.—ED.]

MR. A. DAWSON ON "PHOTOGRAVURE."

To the EDITOR.

SIR,—Will you please allow me to inform your readers that Mr. A. Dawson, of the Typographic Etching Company has kindly consented to deliver a lecture on *Photogravure* at the rooms of the Photographic Society of Great Britain, 50, Great Russell-street, Bloomsbury, on Tuesday, May 17, at eight p.m.

All those who are interested in the subject are invited to be present.

The Assistant-Secretary has organized a small exhibition of photogravures by English and foreign firms. These specimens will be on view from May 17 for a few days.—I am, yours, &c.,

CHAPMAN JONES, *Hon. Sec.*

Photographic Society of Great Britain, Great Russell-street, Bloomsbury, W.C., May 6, 1892.

"SENSITIVENESS."

To the EDITOR.

SIR,—With reference to the discussion that took place at the London and Provincial Association last Thursday evening on *Sensitiveness*, I may as well, with your permission, add that, if two ordinary bromo-iodide gelatine emulsions be made identical in every respect, except that ordinary commercial nitrate of silver be used for one and fused nitrate of silver for the other, the last will be found more sensitive than the first. I do not think that this has been pointed out before, which is my excuse for troubling you.—I am, yours, &c., J. BARKER.

May 7, 1892.

MR. I. GOODSTEIN sends us a circular, in which he informs us that he has "been appointed by the Photographic Society of Great Britain to superintend the hanging of pictures from exhibitors for the annual exhibition," &c. This statement is altogether incorrect, the superintendence of the hanging of the pictures being delegated by the Society to a small Committee of its own members.

Answers to Correspondents.

All matters for the text portion of this JOURNAL, *including queries for "Answers" and "Exchanges," must be addressed to* "THE EDITOR," *2, York-street, Covent Garden, London. Inattention to this ensures delay. No notice taken of communications unless name and address of writer are given.*

*** *Communications relating to Advertisements and general business affairs must be addressed to* "HENRY GREENWOOD & Co.," *2, York-street, Covent Garden, London.*

PHOTOGRAPHS REGISTERED:
Messrs. E. Green & Son, Limited, Manchester.—*Photograph of Mechanism.*

A. J. SIMPSON; H. J. CHANNON; ALFRED WATKINS; G. H. SLIGHT; WM. MATHEWS, and others.—Received. All if possible in our next.

Y. G.—The convergence of the lines is caused by the camera having been tilted.

L. M.—We do not know the price of the book; it is published by Messrs. Jas. Cornish & Sons, of London and Liverpool.

T. R. J. asks: "Is there any solvent for bichromatised gelatine that has been fully exposed to light?"—Try a solution of glacial acetic acid, or a strong solution of caustic potash.

M. CASELY.—Formulæ for the wet-collodion process will be found in the ALMANAC, but space in this column is far too limited to give anything like working details. See London and Provincial report in this number.

C. E. H.—Threaten the man that if he does not return your specimens you will communicate with the Superintendent of Police of his town. If this threat is of no avail, lay a statement of the case before the Superintendent.

SUBURBAN asks if there are good subjects for photography in Kew Gardens, and, if so, is any special permission needed to use a camera there?—Some nice bits are to be had in the Gardens, but a ticket to photograph is required. One may be obtained by application, by letter, to Mr. Thistleton Dyer, at the Gardens.

ALPHO.—Unless you are going a longer sea voyage than just crossing to the Continent, there will be no necessity to have the dry plates packed in a metal-lined case. If the voyage be one of many weeks or months the case is different. Of course there is no objection to the extra protection if cost is not a consideration.

A. M. (Edinburgh) says: "Would you kindly let me know where I could obtain the formula (Mr. Willis's) of the platinotype process of which you speak so highly in last week's number, as I should like to try it exceedingly."—You may obtain the paper and all necessary particulars of the Platinotype Company, Southampton-row, W.C.

R. C. GASSIOT writes:—"I bought a Steinheil 5×4 hand camera and three slides a little while ago and the slides were damaged at the zinc parts. Can you inform me who could do the repairs necessary. I have tried ——, but he thinks it impossible to get them repaired."—Probably some of our readers can give an answer to the question.

A. SIMS sends some examples of his retouching, and asks our "candid" opinion thereon. We regret that we cannot express a very favourable opinion of the work. A great deal of labour has been expended, only to mar the photograph. All rotundity is destroyed, and the face rendered smooth and flat, while the likeness is completely altered. The untouched picture is by far the better.

R. ROACH says: "I want to take the interior of a room that is very dark, having only two small windows of stained glass. I can have the incandescent lights going, but I am afraid the exposure will be excessively long. Would these lights be of any real service?"—The incandescent lights will certainly be of some help; but the best way will be, after the plate has been exposed for some time, to supplement the light with a little magnesium.

A. R. R.—If you are going anywhere on the Continent, except Belgium or Holland, we should advise you to provide yourself with a passport; not that it may be really necessary, but under some circumstances just now it may possibly save some little inconvenience in some parts. One may be had from the Foreign Office by simply filling up a form which is supplied, and having it attested by a banker, magistrate, physician, &c. The cost is but two shillings, and it does for all time.

A PROFESSIONAL.—We do not wish to say anything to wound your feelings, but, from a careful study of your letter, we conclude that the cause of your customers leaving you and preferring the services of your rival may be found in what you rather mistakenly call your independence of manner. An independent spirit is an excellent thing, but it must be largely diluted with tact and suavity when dealing with customers. Never forget the golden dictum that "more flies are caught by molasses than by vinegar."

EMIL A. (Paris), writes, asking whose plates, of English make, we consider the best, and whether they are any better than those made in France?—Our correspondent is probably unaware that it is quite against our rule to express any opinion on the merits of different makers' goods. As to whether English plates are considered better than French ones, that may be, and is, quite a matter of opinion. From the fact that large numbers of English plates are exported to France, it is clear that some people think they are.

HERTS says he is an amateur, and has taken several negatives of friends, and they have ordered copies therefrom. He asks what he ought to charge per dozen, *carte* size. Hitherto, he says, he has charged half-a-crown, but thinks this is not enough.—It is difficult to see how our correspondent can style himself an amateur, seeing that he is trading in portraiture. He should arrange his prices according to the quality of his work and those of *bonâ-fide* professionals in the neighbourhood. But let him no longer class himself as an amateur photographer.

C. WITLEY sends us some pictures with red stains upon them. He says: "These prints have only been done a few days, and you will notice in the delicate portions of them, and in some cases on the faces, a pronounced red staining, though it does not show on the shadows. Can you in any way explain the cause?"—The stains are caused by the mounts. The reddish-brown "enamel" used to surface the cards contains a red pigment that is soluble in water. Hence, when the wet mountant comes in contact with it, solution takes place, and the print becomes stained as complained of. Some brown mounts are very prone to stain the pictures.

F. T. says: "1. *Re* query of last week, my invention is *not* an ordinary actinometer, but an instrument attached to the camera, which works automatically. The only thing necessary is to take cap off lens, and leave it off, the instrument giving a correct exposure to the plate, in any intensity of light, to a fraction of a second. Would this make a successful patent? 2. Can you kindly favour me with the address of Captain Abney? 3. I have taken three negatives of the interior of a church, and on one side of the plates, where a strong light comes between two pillars from a window, there is fogging on one side of the pillars next to the camera. I have examined the camera, which is quite light-proof. Can you tell me the cause of this? Is it the flood of light from the window?"—1. If the instrument does all that you claim, it would assuredly form the subject of a valid patent. 2. South Kensington Museum. 3. Undoubtedly.

BRIXTON AND CLAPHAM CAMERA CLUB.—May 17, *Photo-micrography*, Dr. T. Charters-White.

FALLOWFIELD'S *Remembrancer* for May has reached us, and is, as usual, replete with bargains and the latest things out in photographic manufactures.

PHOTOGRAPHIC CLUB.—May 18, *Reversed Negatives*. 25, *Developers for Bromide Prints*. Outing, Saturday, May 14, Hampton Court. Train from Waterloo at ten minutes past two.

ERRATUM.—In the paragraph on electrotyping in Mr. T. Symmons' paper published in our last, it should have been stated that the copper skin is formed on the wax mould, and the white metal is poured into it after the wax is taken away.

LONDON AND PROVINCIAL PHOTOGRAPHIC ASSOCIATION.—May 19, Monthly Lantern Night and some New Hand Cameras. 26, *The Photographic Study of Clouds and Lightning*, illustrated by slides, Mr. A. W. Clayden. Visitors are welcome.

CHICAGO EXHIBITION, 1893.—The Royal Commission announce that applications for space in the British section can only be received up to Saturday, May 21. Any applications received after that date will be filed, in case of any space becoming hereafter available, but will not be included in the first allotment.

HOLBORN CAMERA CLUB.—Arrangements for May and June:—May 13, *Exposure*. 14, Outing to Epping Forest. Meet at Chingford Station at three p.m. 27, Lantern Night. June 3, *Hints on Landscape Photography*, Mr. H. West. 6, Whit Monday, Outing to Penshurst, Kent. Meet at Charing-cross Station at nine a.m. 10, *Development in Practice*, Mr. E. Clifton. 11, Official Outing to Pinner. Meet at Pinner Metropolitan Station at three p.m. Tea at the "Swan," Ruislip, at seven p.m. 17, Mr. A. J. Golding will lecture and demonstrate on *Carbon Printing*. 24, Lantern Night. Mr. Hodge's slides. Members, please bring your slides and your friends.

CAMERA CLUB FIXTURES:—Monday, May 16, Exhibition, Description, and Discussion of Hand Cameras. Thursday, May 19, Mr. H. P. Robinson, *A Note on Fading, and our Debt to Science*. Monday, May 23, 1. *On Varying the Colour of Platinotype Prints*, by Mr. Rowland Briant. 2. Discussion of Exposure Meters. Messrs. Hurter & Driffield's Actinograph, described by Mr. A. Cowan; Watkins' Exposure Meter, described by Mr. Watkins. Thursday, May 26, Mr. W. Willis, Demoustration of the New Cold Development Platinotype Paper. Monday, May 30, Exhibition and Discussion of Shutters. Thursday, June 2, Mr. A. F. Stanley-Kent, M.A., *Practical Photo-micrography*.

WITH reference to the proposed exhibition at Lincoln of the pictures by English photographers lately on view at Brussels, we learn that nearly the whole of the exhibitors have sent favourable replies to the requests made. The gallery of the School of Science and Art, at the disposal of the Committee, is almost as large as the Pall Mall one, and there are other rooms, and the lecture theatre for lantern exhibitions is also at disposal; so that, beside the show of photography in the principal gallery, there may be joined a lantern exhibition, as well as demonstrations in photography in another room. Possibly other artists will be invited to forward a small selection of their best work, but the Brussels exhibits will be kept to themselves, as a special show. There will be no prizes or awards.

THE BRITISH
JOURNAL OF PHOTOGRAPHY.

No. 1672. Vol. XXXIX.—MAY 20, 1892.

PHOTOGRAPHY AT THE ROYAL SOCIETY'S CONVERSAZIONE.

A more conspicuous example and valuable proof of the great value of the unique position occupied by photography in so many branches of science could not be wished for than that shown at this conversazione. We do not suggest that it formed the apotheosis of the science; but, if proof were needed of the paramount importance of its various modifications, it could be found a hundredfold in the photographs in a multitude of phases that were exhibited on Wednesday, the 4th inst.

Let us first name the astronomical exhibits. Mr. Lockyer had on view a fine spectrum photograph, enlarged twenty-five diameters, of the new star in Auriga taken by a six-inch object glass by the Messrs. Henry, using one of Hilyer's prisms. Also he showed several excellent spectra of stellar objects illustrating points in the meteoric theory. He had, further, photographs of the large reflector (nearly three feet) at Kensington, which is now nearly completed. Mr. Roberts showed various photographs of celestial objects, including the original negative of the Nova Cygni taken with a twenty-inch reflector, the exposure being two hours.

The Solar Physics Committee exhibited what is considered the best series of sun-spot pictures yet produced. They included the great sun-spot visible last February.

Of physiographic interest was the collection of pictures, over a hundred, illustrating coral reefs, coral animals, and the marine fauna generally of the Great Barrier district of Australia. One point of interest in connexion with some of these views was the fact that accurate measurements of some of the reefs photographed had been taken, and thus further growth could be exactly measured.

The archæologists would find much to interest them in the views of Central American monuments and buildings from the ruins at Chichén Itzá (Yucatan), while the anthropologically minded could study the development of racial qualities in a series of over a hundred views of a wrestling match between a black and a white man, the representative of civilisation evidently getting the worst of it.

Students of artillery were afforded an opportunity of examining a remarkable instrument for measuring the velocity of projectiles. In connexion with the electric tram, chronograph photography was utilised to obtain the measurement of the velocity of projectiles, and small periods of time in physiological research, and to the photography of insects and falling drops of liquid. The electric spark is the illuminant, the plate being fixed in a "carriage" forming part of the instrument.

Mr. Boys' name is already familiar from his study of falling drops, aided by photographic means; and at the conversazione his exhibit was, perhaps, the most unique among many truly remarkable ones. They consisted of a series of photographs of bullets shot from a rifle taken by a modification of the old method. The remarkable point in the views was the air waves caused by the rapid flight of the projectile; they appeared in the photograph like the waves produced by a steamer when steaming fast ahead. One slide actually showed the small particles of paper torn out of the screen as the bullet passed through. They were seen rushing through the air, and producing their own air waves, quite as clearly shown as those of the bullet itself. A bullet passing through a wire was photographed, the camera seizing the piece of wire broken off before it had time to fall. A photograph of a magazine rifle bullet piercing a sheet of glass was also to be seen. All the particles and splinters of glass were taken, and, strangely enough, their direction of motion was opposite to that of the bullet itself. Some idea of the neatness and skill required to execute these results will be formed when we state that the various rapidities with which the bullet travelled were from 750 to 3000 feet per second. There was a remarkable exhibit, mention of which, from its connexion with optical or, at any rate, ocular matters, should not be omitted. It was an electrical retina, and shown by Professor Oliver Lodge, and possibly illustrated the meaning of the well-known rod and cone system of the retina of the eye. Radiation from spheres which were in a suddenly disturbed and oscillatory electrical condition were made to fall upon a graduated series of end-on cylinders, which responded by vibrating transversely.

There were many other noteworthy objects too numerous to mention in this brief survey; but we have, we are assured, already more than shown how great a part photography plays in science at present; what it may not do in the future it is difficult to prognosticate.

A QUESTION OF EXPOSURE.

It was commonly said, in the early days of gelatine plates, and no doubt with perfect truth, that half the plates were spoilt by over-exposure, for it was difficult to realise all at once the great advance that had been made in sensitiveness. Moreover, at that time, the plates themselves were not of the character that would bear to be taken liberties with, and comparatively slight departures from the proper exposure, aided by the then less perfect knowledge of alkaline development, sufficed to produce failure. Over-exposure gave results, however, less disastrous than the reverse, and, as it also tended in the direction of a peculiar kind of softness and delicacy of detail unfamiliar to workers of the older processes, it grew almost into a habit, until the cry of want of "sparkle" set photographers to work to attempt better results.

Nowadays, perhaps, the tendency is quite in the opposite

direction, for the great fuss made about the "new instantaneous process" has so imbued the minds of new workers with the idea that everything must be done with the drop shutter, that snap-shots have become paramount, and nothing that is not 'instantaneous" is considered by many worth attempting. The consequence is that a far larger proportion than half of the prints one sees produced by amateurs of the present day are spoilt by under-exposure, and have not even the merit of being interesting as *coups de main* or studies, since all the work except the development is performed by the shutter and the subject.

Since the now general adoption of exposure tables and meters, it might be thought that errors in exposure would cease; but there are various circumstances to be taken into consideration as explaining the reason why it is not so. In the first place, it should be remembered that, however perfect may be the instrument, the tables, and the system of calculation employed, there must always be something left to "judgment;" and too frequently the personal element intervenes to upset their accurate work. Again, while very many—perhaps it would be more correct to say the vast majority—do not use any of these extraneous aids to correct exposure, those who do are too prone to take the actinometer and its tabular assistant quite literally, or perhaps even to strain a point or two in order to make the exposure as short as calculation will possibly permit; and thus, while firmly believing that they are working by correct rule, they are in reality under-exposing.

Now, there is really no necessity—no excuse—for systematic under-exposure except in the case of subjects that must, perforce, be taken with some form of rapid shutter; and even here the practice should be confined to subjects that are worth it, or rather to subjects whose interest lies outside the bounds of pictorial art, for what value, artistic or otherwise, can attach to a photograph that is technically imperfectly executed? For scientific or other purposes it may be necessary or desirable to secure transcripts of scenes or incidents that require the use of the quickest shutters, but no artistic treatment—whose sole value, in fact, consists in their being accurate and indisputable evidence in a graphic form. Here under-exposure may be excused, nay, must be tolerated, since it is probably "Hobson's choice" in most cases.

There is, perhaps, some excuse, though no necessity, for making excessively rapid exposures when the artistic character of the result would suffer more from the movement of the objects portrayed than from the want of technical perfection in the photograph; but such subjects are extremely rare, as most moving scenes or groups that present any features of artistic or other interest can be readily secured with exposures of such comparatively long duration that, with suitable lenses, will give a photographic result of good, if not of perfect, quality.

In the pre-gelatine days there was not only every excuse for shortening the exposure as much as possible, but often it was practically impossible to expose long enough. The drop-shutter men of to-day know little or nothing, most of them, of the days when exposures running into *minutes* in full summer sunshine, or perhaps into hours in diffused light under less favourable circumstances, were by no means unknown to the workers of dry plates; and when, even with the quickest wet plates, an open landscape might require twenty or thirty seconds. There hangs not far from us as we write a photograph of somewhat large size, taken about a quarter of a century ago, an open view, which received, if we remember rightly, an exposure of an hour and twenty minutes, but that was before lenses of the modern "rapid" type had come into general use. Another instance we remember of an amateur who wished to get the interior of a church for the vicar, and who, after one or two unsuccessful efforts, was reduced to the necessity of setting up his camera after service on Sunday evening, as it was inconvenient to do so on Monday morning, and leaving the plate to expose until he was compelled to remove it in time for service on the following Wednesday evening; and, even then, owing to the non-actinic colour of the glazing, the time was far from sufficient.

Then, we repeat, little blame could attach to any one who curtailed his exposures to the utmost possible limit; yet there was far less done in that direction than at the present day, for the amateur of the period was a steady-going methodical being, whose object was pictures—results worth showing. Looking back at some of the best-known and remembered workers, both wet and dry, and with whose works we are familiar, they are invariably men who favoured long exposures; and we venture to assert that, if the best pictures, wet or dry, of bygone times could be examined, and the details of their production given, they would all be found to have had long exposures.

We were present at an out-door meeting of one of the London Societies a few years back when one of the members was making drop-shutter exposures, the subjects being pure landscape. Another member, an "old stager" of the wet-plate days, rallied him on the subject, delicately hinting that he could scarcely hope to get any decent results with such short exposures. Our shutter man argued the point, averring that with the light and general conditions prevailing a fraction of a second was quite sufficient for *him*, and finished up by pointing at the landscape before them and exclaiming, "Now, then, look there! You could do that in a tenth of a second." "Oh, yes!" was the dry reply; "I could *do* it, *but I don't want to waste a plate.*"

While there is nothing, beyond what we have already admitted, to be said in favour of curtailing the exposure, there is very much, if not everything, to recommend the giving of a full exposure even if it should extend as far as slightly *over*-doing it. Without making any great use of the hackneyed phrase, "latitude of exposure," we may remark, and few will contradict us, that a variation of ten per cent., or even more in the exposure, in excess of what is absolutely necessary to give a first-class result, will have absolutely no effect in depreciating the quality of the result, and very much greater departures may be made from the normal with practically no ill effect if the plates be good ones. The plates which suffer most seriously from slight over-exposure are not, as many suppose, those that are most rapid, but those which suffer from some defect in preparation, chiefly from want of "body," but also from some kinds of inherent fog. A well-coated and clean plate will stand a considerable amount of exposure in the camera in excess of that absolutely necessary without showing any ill effects; not so in the case of under-exposure, for every fraction of a second of deficiency means a corresponding deficiency in the action of light, which cannot be made up by any modification of development. Therefore, while there is no inducement to, or excuse for, under-exposure—except the ill-judged rage for "snap-shotting"—there is, on the contrary, every reason for giving a full and a fairly good excuse for over-exposure, if habit should gradually lead in that direction.

But, it may be asked, what are the advantages, or, rather, what is the use of running the risk of over-exposure, when a

correct exposure will answer perfectly, and can be arrived at by means of calculation? Well, the use, the advantage, is just this, that, as slight over-exposure does no harm, it will keep us on the safe side of accidents, at any rate. Nothing or nobody is infallible, whether we look at actinographs and tables or at human beings. The former may be perfect as machines, but, to some extent at the mercy of the "judgment" of the latter, they are helpless to secure perfection in the results given. If, therefore, an error occur on the *under* side, a barely sufficient exposure becomes converted into under-exposure, which is bound to damage the quality of the result. With an already slightly excessive exposure, another small error in the same direction matters very little, and therefore, we claim, no possible harm can be done, but good may result, from systematically adopting our recommendation.

As an illustration of this, some years since we had a "day out" with the camera, the slides being partly filled with "Instantaneous" and partly with "Ordinary" plates, which differ very considerably in sensitiveness. By an error, which we did not detect until we came to develop, we found we had wrongly exposed the two kinds of plates, which had been placed, the one in the earlier numbered slides, and the others in the later; but we had somehow mentally reversed them, and the slow plates had had the shorter exposures. However, thanks to our invariable habit of giving full exposure, they had had sufficient, while the more rapid ones, with far longer exposures, were well within bounds of development, and every plate of the dozen made a good negative. If our practice had been to give the shortest "correct" exposure possible, one-half of the plates would have been lost.

But, further, there is this to be borne in mind, a well-exposed plate develops more rapidly and with a weaker developer than one that has been only just sufficiently timed. Consequently, it is exposed for a shorter period to the chances of fogging by light in the dark room, or of staining by the developer, and any slight fog that exists in the film itself is less likely to be brought out than would be the case when the development required to be more prolonged or more energetic.

We might go on enlarging on the advantages of systematically giving what is termed a "full" exposure, which we ourselves consider a proper though others may deem it an over-exposure; but we think sufficient has been said to show the unwisdom of adopting the opposite course. However, as the season is about opening, we beg our readers who have not already done so to try the plan, and compare the results with those obtained by cutting the time as fine as possible.

Mr. Valentine Blanchard.—This veteran photographer, who has been honourably associated with many phases of the art science for a long span of years, is about to retire from active photographic work. Mr. Blanchard has always identified himself with the art aspects of photography, upon which his dicta have commanded general respect. He will, in future, reside at Harston, in Cambridgeshire, with the intention of devoting himself entirely to literature, as a profession, into which we are sure he will carry the good wishes for success of his many friends.

Mr. Ives' Second Lecture.—On Tuesday last, at the Royal Institution, Mr. F. E. Ives delivered his second lecture on *Photography in the Colours of Nature*. The syllabus was as follows:—Sensitive plates and selective colour screens used in composite heliochromy—Special cameras for composite heliochromy—Different methods of superposing the three coloured images—The triple lantern—The heliochromoscope—Permanent colour prints—Exhibition of results by optical lantern projection. A number of very effective views of Yellowstone Park were projected on the screen, as also the picture of a bunch of multi-coloured flowers. The latter, it was stated, was taken on an Edwards's Isochromatic Plate.

M. Lippmann's Latest Advances.—Before the Académie des Sciences on April 25, M. Lippmann stated that using albumeno-bromide plates, orthochromatised by azaline and cyanine, he had obtained brilliant spectrum colours, including red, without the interposition of coloured screens, and with an exposure of from five to thirty seconds. Two of the plates viewed by transmitted light showed the colours complementary to those seen by reflection. He showed four plates, having faithful representations of a coloured window in red, green, blue, and yellow; some coloured drapery; oranges and poppies together; and a multi-coloured parroquet. The drapery and the bird had an exposure of from five to ten minutes in electric light and sunlight, the other objects taking some hours in diffused daylight. A blue sky was rendered on the plate as indigo.

"How to ascertain when the Fixation of a Silver Print is Complete."—Had that amusing conception of the novelist's brain, Mr. Richard Swiveller, been a photographer, he would surely have characterised a question from the box, which was read at the last meeting of the London and Provincial Photographic Association, as an "unmitigated staggerer." The questioner wished to know "how to ascertain when the fixation of a silver print is complete?" The information forthcoming constituted no clear answer to the question, which, it appears, was put to the students who sat for a recent City and Guilds Institute examination in photography. It was finally decided to ask Mr. Lyonel Clark, the examiner on that occasion, to furnish the answer to his own question "for the benefit of photography." Photographers, we are sure, will be very pleased to have the information.

"Natural-Photography."—As a result of several years' experimental work, and aided by eminent opticians and others, Herr Eugene Hackh, of Stuttgart, has, it is said, succeeded in perfecting a method of taking instantaneous portraits in the size of the original, and, we suppose, larger if necessary. Inasmuch as the method is to form the subject of a patent in this and other countries, no details are yet available, but it seems that M. Hackh employs an artifical illuminant of his own invention, which is ignited by explosion, without casting harsh lines on the face of the sitter or inconveniencing him in any way. The full power of the light is utilised by a special system of reflectors, of which we are unable to obtain any particulars. The results are spoken of by painters and others as possessing great artistic merit, while practical photographers are said to regard the process favourably. It is even hinted that it will interfere with the business of professional enlargers. We shall see.

Photographing on the West Pier, Brighton.—In reference to Mr. George Grossmith's recent passage of arms with the authorities of the West Pier, Brighton, who, being unaware of his distinguished identity, refused to allow him to take photographs from that structure, we are informed that the necessary permission is granted on payment of 2*s.* 6*d.* This is about 2*s.* 4*d.* too much to an ordinary member of the public, and, on the authorities' own showing, exactly 2*s.* 6*d.* in excess of the charge to be expected from a popular comedian. Evidently, kissing goes by favour at London-super-Mare. We understand that the restrictions on photography in Preston Park have been withdrawn for the present, although the use of the camera is still interdicted in Steyne Gardens. It would be an admirable thing if Photographic Societies at popular places of resort would make it their business to endeavour to remove the rules against the taking of photographs on piers, &c., where the holiday-makers most do congregate.

Photogravure.—There was a capital attendance at the Photographic Society of Great Britain's extra meeting on Tuesday night to hear a lecture by Mr. A. Dawson, of the Typographic Etching Company on *Photogravure*. If there was any expectation that Mr. Dawson would go into the practical details of the process which he and others work with so much skill and success, nothing but disappointment was the result. In that regard the meeting dispersed in just about the same state of wisdom as it gathered, Mr. Dawson contenting himself by confining his remarks to the economic and artistic aspects of his subject, and making brief references to the outlines of those photogravure processes which are to be found in all the text-books. There is a small but admirable collection of photogravure work on view in the Society's rooms which is well worth inspection, Messrs. T. & R. Annan & Sons, W. L. Colls, Paulussen (Vienna), the Typographic Etching Company, Annan & Swan, the Autotype Company, and Haenfstangel (Munich) contributing examples of their work. Messrs. Annan & Sons' reproductions of oil and water-colour paintings are, particularly the latter, extremely fine. Indeed, all the specimens are difficult to separate critically.

Painters and Photography.—It is usually very amusing testimony that is given by artists—painter artists we refer to—when they are called upon to give evidence, as experts, in a court of law. Notably was this so at Bow-street recently, in the case of Mr. Rudolph Blind's work, *The World's Desire*, as to whether it was an indecent picture. According to a report of the proceedings, Mr. Frederick Goodall, R.A., said, "You never got a perfect figure in nature. It was necessary to idealise. Photographs from the nude were offensive, and the proportions were always wrong." There is no gainsaying the fact that the majority of photographs from the nude are offensive—nay, more than that—but there is no reason why they should be, when artistically treated, any more than is a painting from the nude, similarly arranged. We have seen many that were less so than some paintings that have been publicly exhibited. Mr. Goodall says that proportions in a photograph are always wrong, and that you cannot get a perfect figure. Poor photography, and poor nature, both wrong again! If photography so misrepresents, why is it that painters make so much use of it in their work? Why do they have their models photographed? Why do they often paint their landscapes almost entirely from photographs? Surely they cannot use them to see what to avoid. The pictures to be seen in the different exhibitions—the Royal Academy, now open, not excepted—proves the contrary. Why, then, should painters decry that which is of so much assistance to them? But there, some do not, but graciously acknowledge its value to them.

OBSOLETE PROCESSES.

No. 2.—Calotype.

From the earliest time of working the calotype process, the invention of the late Mr. H. Fox Talbot, it was found that the paper employed—just as it is in the present day in all silver processes—was an important factor in the case. Unless it was of the right character, good calotype negatives were an impossibility. The make of paper most in favour with the majority of workers was that bearing the watermark of "Turner, Chafford Mill," which used to be supplied—if they were not the sole agents for it—by Messrs. Horne & Thornthwaite. Although this brand of paper was at one time in such high repute, it is now quite unknown in connexion with photography.

The first thing in the preparation of the paper was to iodise it, which was to obtain in, and upon, it a perfectly even coating of iodide of silver containing neither an excess of silver nor of iodine. This was done by treating it first with a solution of nitrate of silver of from fifteen to twenty grains to the ounce of distilled water. Different operators had different methods of applying the solution. Some applied it with a flat camel's-hair brush; but, as that was liable to disturb the texture of the paper—a very undesirable thing to do at this stage—the more favourite method was to spread it over with a glass rod. The paper was placed on several sheets of blotting-paper, then the rod was laid on one end of the paper to be prepared, and a little of the silver solution poured along it. Then the rod was passed to the other end with an even sweep, carrying the solution before it, the excess being driven off to be absorbed by the blotting-paper. The paper was then hung up to dry spontaneously.

When dry, it was floated upon a solution containing about twenty grains of iodide of potassium and four or five grains of cloride of sodium to the ounce of distilled water. The time of floating was of importance, inasmuch as, if the paper were left too long on the bath, some of the iodide of silver first formed would be redissolved, iodide of silver being soluble in excess of iodide of potassium. The time allowed was generally from thirty to forty seconds only. When removed from the bath, and slightly drained, the paper was laid horizontally—face upwards, of course—so that the solution would be evenly absorbed, and thus convert the whole of the nitrate into iodide of silver—an important point—otherwise marks or stains would arise when the negative was developed.

Now, it will be seen that the paper, at this stage, contained not only the iodide and chloride of silver, but also the nitrates of potassium and sodium, resulting from the double decomposition of the silver nitrate with that of the potassium and sodium salt, as well as an excess of iodide of potassium. All these substances had to be removed before the paper was sensitised, and, as the outer layer of iodide of silver was but loosely adherent to the surface of the paper, this had to be carefully done. When the paper had laid till it had become partially dry, it was floated for ten minutes or so, face downwards, on one or two changes of distilled water. After this treatment, the paper was dried, when it had a perfectly even coating of the yellow iodide of silver. In this condition the paper would keep for a long period without deterioration, provided, of course, it was preserved in the dark; hence it was usual to prepare a good stock at a time.

For use the paper had yet to be sensitised. This was done with "gallo-nitrate of silver." Two solutions were prepared, one a saturated solution of gallic acid in water; the other, forty grains of nitrate of silver and one drachm of acetic acid to the ounce of water, distilled water being used in each instance. These solutions had to be mixed in equal proportions just before they were applied to the paper, as after mixing they rapidly decomposed. There were several methods of applying the sensitising solution. The most common one was to place a clean glass plate, somewhat larger than the paper to be treated, upon a levelling stand, and pour on, and evenly distribute it with a glass rod, the mixed solutions. Then, taking the paper by the opposite corners, it was gently laid on the solution, in the same manner as in sensitising albumen paper, when it was allowed to remain for from ten to twenty seconds. It was then floated on, and finally washed in several changes of distilled water. The paper, when sensitised, would not keep more than a day or two, in hot weather less. It was usually exposed, while still moist, between glass plates, which served the double purpose of keeping the paper flat and preserving it in a moist condition. Double dark slides, similar to those now in use, were generally employed for the purpose.

If enhanced sensitiveness was desired, a stronger solution of nitrate of silver was used, and the exposure made immediately after preparation, as, the more sensitive the paper was rendered, the shorter time it would keep. As compared with the modern plates, the exposure was very long, but with a portrait combination and a good light a portrait could be taken in the studio in from twenty to sixty seconds. With a landscape lens having an aperture of about *f*-30 out of doors, the exposure would be from three to ten minutes in a fair light. If the exposure had been very full, or the paper was kept for some time between exposure and development, a more or less faint image was visible on the paper when removed from the slide by reason of the developing action of the gallic acid present.

The developing solution was similar to that used for sensitising, namely, gallo-nitrate of silver, except that, generally, it contained rather less silver. It was usually applied in the same manner—the solution was poured on a glass plate, and the print floated face downward upon it. If the image was tardy in making its appearance, as it used to be when the temperature was low or the picture was underexposed, heat was applied. A hot iron was usually held an inch or two from the back of the paper. Sometimes the heat was applied locally, to force out detail in the shadows that could not otherwise be obtained.

As soon as the development was completed, the negative was quickly washed in several changes of warm water, to stop further action of, and to remove, the developing agent. Then it was pressed between folds of blotting-paper, to remove all excess of water before it was put into the fixing bath. That was simply a dilute solution of hyposulphide of soda; an ounce of the salt to a pint and a half of water was about the usual proportion. The time of immersion was from five to ten minutes. After removal from the fixing bath, the negatives were again pressed between blotting, to get out as much as possible of the solution before they were put into the washing water. During the washing it was very customary to blot the pictures off between each change of water. After washing, the pictures were dried, and, very frequently, ironed with a hot laundry iron; and, to facilitate printing and also with the view to ameliorate the granularity of the paper they were often rendered transparent by waxing.

By the calotype process, notwithstanding its troublesome manipulation, its slowness, and the fact that the negatives were on paper, good pictures used to be obtained, which would yet bear a fair comparison with those produced nowadays, particularly if they are of large dimensions.

AMERICAN NOTES AND NEWS.

Death of Mr. J. Moss.—We are sorry to learn of the death of Mr. J. C. Moss, the founder of the Mosstype Engraving Company, New York, said to be one of the largest firms of its kind in the world. Mr. Moss commenced his experiments in process work so far back as the year 1858. The method which his Company has been so extensively working for many years was not patented, some of the most important elements in it being, it is stated, not of a kind that a patent would protect. Mr. Moss was only fifty-four years of age, and owed a large share of his success to the assistance and devotion of his wife.

"Aristotype" in America.—Collodion and gelatine emulsion papers, which so far, in this country, have not secured more than a moderate share of public favour, appear, in America, to have obtained very great popularity. Their manipulation and treatment form the chief topic of discussion in the photographic papers just now, and the portrait studies which our contemporaries delight to present to their readers are generally printed on aristotype. The competition and rivalry among the makers of the various commercial brands is very keen, which the *American Journal of Photography* thinks should surely produce a perfect paper in the near future. This rather discounts the qualities of commercial papers at present available.

Complicated Formulæ.—In two of our American exchanges we find protests against the multiplicity of ingredients included in many of the formulæ given for the combined toning and fixing bath for prints of the emulsion class. One of these extraordinary baths is made up of hypo, ammonium sulphocyanide, lead acetate, alum, acetic acid, citric acid, lead nitrate, gold chloride and water, in all nine substances. We can fully understand the part that each of these bodies is supposed to play in toning and fixing, but we strongly question whether the individual action really takes place; and, even if it did, we don't admit the necessity of it. Such formulæ are perplexing and troublesome in the extreme, and we shall do our best to discourage the epidemic of faddishness and mock photo-chemical science which is responsible for their production.

To Remove Silver Stains from Negatives.—The *Scientific American* indicates the following as an effective remedy. Having dissolved off the varnish, mix the following solutions, and apply:—

A.—Ammonium sulphocyanide	½ drachm.
Water	1 ounce.
B.—Nitric acid	½ ounce.
Water	1 ounce.

A fresh solution should be made for each negative, which should be finally washed and treated with chrome alum. Perhaps our many correspondents who, are constantly asking us to indicate the best means of removing silver stains from negatives without injuring the deposit, will try the method suggested.

Prices in Canada.—According to the *Canadian Photographic Journal*, the photographers of Ottawa lately came together, and agreed not to work at less than three dollars per dozen pictures, cabinet size, we suppose. We learn from our contemporary that at present work is being done at ruinous rates in various parts of the Dominion, and especially in Ontario. In Quebec better prices and more harmony prevail among photographers, but elsewhere the hostility to the "cut-throats" and "Cheap Johns" is of the bitterest nature. There are many English photographers who will be able, without much effort, to sympathise with the feelings of their Canadian *confrères*. We also gather that the Canadian dealers have adopted a slightly increased price-list, the list being signed by every dealer of note in Canada. Some dealers would like to accomplish the same sort of thing in this country, we believe.

A New Toning Bath.—Mr. John R. Clemmons, of Philadelphia, has lately been experimenting with the aluminium salts as toning agents for silver prints, and at the last meeting of the Photographic Society of Philadelphia showed some plain silver prints toned in the ordinary gold bath with the addition of aluminium chloride. Warm brown tones of great beauty, it is said, result with very clear whites. The bath is made up as follows:—

Aluminium chloride	20 grains.
Bicarbonate of soda	85 „
Water	12 ounces.

Half an ounce of gold solution 1 : 15 is added. It is stated that prints in a 1 : 6 hypo bath fix in about five minutes, and that there is but a slight change in the tone produced. The whites of the prints remain quite clear, and the details in the shadows are remarkable.

Inaccurate Description of Lenses.—Before the Photographic Society of Philadelphia, on March 9, Mr. W. A. Cheyney read a short and, on the whole, sensible little paper, pleading for a more accurate description, by the opticians, of photographic lenses. Theoretically, we agree with him that, in stating the covering power of a lens, it would be better to have indicated the diameter of the circle which is sharply delineated, instead of the size of the plate; but in practice we believe it would create confusion in the mind of the unreflective amateur, who, as a rule, understands his lens less than any other item of his photographic equipment. Mr. Cheyney quotes some manufacturer as saying that photographic objectives are not instruments of precision, and very neatly remarks that, if they are not, we are paying too much money for them. We hope, in defiance of Mr. Cheyney's assurance to the contrary, that it is the exception, and not the rule, that the stated equivalent foci of American lenses vary half an inch or so from the actual measurement.

[Since writing the above, we deeply regret to learn that while visiting New York, Mr. Cheyney suddenly dropped down dead while purchasing a ticket at one of the railway stations.]

A NEW FORMULA FOR THE DUSTING-ON PROCESS.

Comparatively few modern photographers have any practical knowledge of what is known as the "dusting-on process;" and, though it is frequently mentioned in these columns, it is very rarely that any attempt is made to arrive at an explanation of its meaning and uses. And yet it is a process that, more almost than any other of those not strictly falling within the lines of negative and print production as generally understood, lends itself to many purposes.

It is not so much in the direction of the production of vitrified enamels, enlargements, and reproductions on a large scale, and other similar uses to which it was originally put, that we may look for its adoption at the present day, but rather to the reproduction and modification of defective negatives, the introduction of skies and clouds, the production of opals, and even of transparencies of large size for decorative purposes, to all of which uses it is peculiarly adapted.

Although many formulæ have been published for the sensitising liquid—and several are given at the end of the Almanac—none have proved hitherto entirely satisfactory, except in the most careful hands. Of the various ingredients—gum, gelatine, sugar, glucose, honey, glycerine—some are more manageable than others. The best formulæ

are the simplest, and, if it were possible to work with only a single organic element, that method would be the one I should adopt. Unfortunately, however, this is not the case, as there are varying condition, to satisfy which necessitate the employment of different substances and not infrequently the alteration of their proportions.

Gum arabic has usually been the favourite substance employed to give body to the film, but it is inclined to present difficulties in coating the glass, and also to blister in the operations subsequent to development. Still it is better than gelatine, which either does not take the pigment freely, or else flies to the opposite extreme and takes it indiscriminately, causing smears and veil which utterly ruin the result. Of the hygroscopic agents, sugar and glucose—that is, cane and grape sugar respectively—has each its supporters, the latter being, perhaps, the one that exhibits most body, as well as undoubtedly the highest attraction for moisture. Honey, another form of saccharine, is in some respects, perhaps, superior to either, since its non-saccharine constituents give to it a "body" which renders it capable of use alone or in conjunction with glucose if care be exercised in the various manipulations.

The trouble experienced in using the saccharine substances alone, that is, without some non-hygroscopic matter, arises not from any insensitiveness or inability to form an image, but, perhaps, rather the reverse of the latter, the too great *readiness* to take the powder. A film of glucose and bichromate alone will *commence* development as satisfactorily as any by the most elaborate formula; but, owing to its highly hygroscopic character, a stage is soon reached at which it becomes unmanageable, owing to the rapidity with which it attracts moisture when the heat of the plate is entirely gone. The alternative is to be content with a coarse and "smudgy" result, or to be constantly redrying the film and starting afresh, which is, to say the least, a tedious and troublesome process. The presence of a little gum or gelatine, by hardening the film, reduces the tendency to excessive affinity for moisture, and so brings the manipulation within the range of convenience.

Chief among the mechanical difficulties must be reckoned that of securing a perfectly smooth film, entirely free from dust or other specks. It will be readily comprehended from the very nature of the process, both as regards composition of the film and modified development, that any inequalities of surface must be in the highest degree detrimental to success. As a matter of fact, a minute speck of dust in the film forms a nucleus round which, at every sweep of the brush, more and more of the powder collects, until the once scarcely visible point becomes a hideous blemish. This form of trouble arises in two directions: in the difficulty of closely filtering the viscid and syrupy solutions; and in the proneness of the coated film to attract and arrest floating particles.

In the first respect, an entirely new solution I have been recently using is far superior to any other I have hitherto tried, and it is, at the same time, free from the special faults peculiar to those substances I have already named. Indeed, it is not to much to say that it almost puts a new aspect upon the working of the dusting-on process, so greatly are the manipulations simplified.

The chief variation from the ordinary formulæ lies in the substitution of mucilage of linseed for the gum arabic or other non-saccharine matter, and with this may be combined either best English loaf sugar or, preferably, sugar-candy. Glycerine is frequently added to increase the affinity for moisture in specially dry weather, though I always prefer to submit to slower development, rather than resort to its use, when possible. More reliable than glycerine, however, I have found to be the finer grades of molasses known as "golden syrup," the particular sample I have used successfully being a highly refined kind, sold in tins, and known as "Lyle's golden syrup." The advantage of this over glycerine is that it is less violently attractive of moisture, and therefore less liable to "rush" the development when used in full quantity.

The formula I have been using consists of the following ingredients:—

Mucilage of linseed	20	ounces.
Sugar candy (or loaf sugar)	1	ounce.
Liquor ammoniæ fort.	½	"
Potas-ium bichromate	1	"
Golden syrup as required.		

The linseed mucilage is made as follows:—Take a moderately heaped teaspoonful of clean *unground* linseed, wash it in two or three changes of cold water to remove dust and dirt, and allow it to soak for some hours. The husks will then be found to be surrounded by a glazy mass of gelatinous mucilage, and the whole should then be transferred to an enamelled saucepan and raised to the boiling point, stirring well the whole time. After simmering for five or ten minutes, remove from the fire, and when ebullition has ceased, if the liquid be thick or "ropy," add more water and strain through fine muslin, while still quite hot, to remove the seeds. Afterwards filter more closely in front of the fire, to keep the liquid hot, and then allow to cool; and still further thin if it flows unevenly when poured on to glass. When quite cold add the ammonia, and, after some hours, again filter, and then set aside for some days, until the liquid becomes quite clear and bright and has deposited any flocculent matter that may be unremovable by filtration.

The bichromate of potash should be added in crystals a short time before required for use, and, if convenient, the solution should be heated, filtered, and used warm, a finer and more even film being obtained in that way. When newly mixed, the sensitive solution is a bright yellow orange colour, which gradually changes to a brownish tinge with age. It remains useable, however, if kept in a cool, dark place, for some days, but should be thrown away when very dark.

W. B. Bolton.

THE CAMERA AND THE CONVENTION; OR, PICTURESQUE SCOTLAND AND PHOTOGRAPHY.

III.

West from Edinburgh, Linlithgow stands out as the first place of interest. At Linlithgow Palace Mary Queen of Scots was born. Two or three hours can be well spent here. We remember seeing a very artistic view of this palace, with a bit of the loch in the foreground. It was a photogravure, produced by Mr. Balmain, of Messrs. Tunny & Co.'s, also from a negative of his own, we think. It was given as a presentation print by the Edinburgh Photographic Society. This picture must be familiar to many and it is a good illustration of what can be done at Linlithgow. There is the "Cross Well," and St. Michael's, a good specimen of the ancient Scottish parish church. The village itself is not picturesque.

On proceeding to Stirling we pass Bannockburn, but there is nothing of photographic value there. Of course, there's the "Bone Stone," in which the Royal standard was raised, still to be seen, but it is below the level of the ground, and protected by railings.

Stirling.

Stirling is a good centre, with its hilly town, its castle of renown, and its marvellous winding Forth. Some time should be allowed to do this historical place justice. The interior of the castle alone would supply a day's work for the camera. The view from the battlements of the castle is beautiful, and embraces a very extended area, the windings of the Forth, from this elevation, showing well, trailing and twining out and in like the twisting of a serpent. But, to enjoy the pleasures of this phenomenal stream, the best way is to come to Stirling by steamer from Granton, in a line of seven miles from Alloa to Stirling—these turnings take up a waterway of over twenty miles—and as you approach Stirling by boat the changing position of town and surroundings is very puzzling—now in front, now behind, changing every minute, until you begin to wonder if ever you will reach Stirling at all.

The castle and the town can be photographed from many points with advantage, so that a walk round before beginning to work will tend to the saving of plates, besides giving you the points that commend themselves to you as the most effective and pleasing. We have taken some good pictures of the town with the castle in the background, and the river Forth in the foreground—from near Combuskenneth Abbey. This abbey and surroundings are worth a plate or two, although the abbey itself is too square and plain for artistic effect. After photographing the places of interest in town, there is the Wallace Monument within an easy distance, and, a little further on, a good general view of Bridge of Allan may be had.

Bridge of Allan and Dunblane.

From Bridge of Allan to Dunblane there is three miles of river scenery rich in effects. Dunblane, as a village, is not any use photographically. The cathedral may be worth a plate or two, but it has been renovated lately, and not improved. From the other side of the water, with the river in the foreground, is, we think, the best point for a picture of the cathedral.

From Stirling a good day's outing may be enjoyed, going by rail to Rumbling Bridge at Dollar. The river Devon, in this vicinity, is rich in waterfalls and foliage, and, to be compressed into so small a compass, contains some of the most beautiful effects we have ever seen. Here, also, Castle Campbell, the old fortress of the Argyll family, stands, high up on the hill over the village of Dollar. It is a considerable pull up to the castle, but it is worth the trouble. Instead of by rail, we have driven from Stirling to Dollar, a distance of some twelve or fourteen miles along the base of the Ochil Hills, passing the villages of Menstrie, Alva, and Tillicoultry on the way. In the hills behind Alva there is a very picturesque glen and waterfall, where we have spent half a day very enjoyably with the camera.

Donne Castle and Callander.

From Stirling to Callander is about an hour's journey. On the way a halt might be made for a couple of hours at Donne, to get impressions of Donne Castle if desired. It is not easy to get pleasing pictures of this ruin, it is so square and plain; but, by crossing the river and ascending the hill opposite, we managed to get a good view of the side of the castle, the trees that grow on the embankment of the stream breaking in upon the long, straight lines of masonry, and giving a fairly successful result.

Callander is the flood-gate to some of the finest scenery in Scotland. It is a pleasure beyond compare to stand upon the bridge that spans the Teith and look upon the ever-varying landscape stretched before you, with shimmering rivers glistening in the sun, and shaggy hills that mount up from the plain higher and higher until reflected against the sky they reach a climax on Ben Ledi's head.

Callander as a centre would delight the lover of landscape for a long time. The nearest place of interest to the village is Bracklinn Falls. They are situated on the River Kelty, and are about a mile and a half distant. They are wild and precipitous, and form a very interesting study. From the river bed some of the best pictures are taken.

The River Leny.

The Leny is on the other side of the village from Bracklinn. It is a river that runs from Loch Lubnaig to the Teith. Loch Lubnaig is five miles from Callander, and the road to it is called the Pass of Leny. About a mile out from Callander we strike upon the Leny, which from this point runs close to the road all the way to the loch. Every foot of the way is filled with pictures of mountain and flood, of rapid and of waterfall. On the way, and nearer the loch, we come upon what is called the Chapel of St. Bryde. Once upon a time we went to photograph this chapel, being led to suppose that it was a ruin of some importance. When we got there we found nothing to photograph but a little bit of a dyke like a sheep-pen, or the boundary wall of an old churchyard. You can imagine how disgusted we were. Just beyond this is Loch Lubnaig. Should there be no boats on the water, this loch does not compose well. The stretch of water is too expansive, and the hills around too distant to make an effective picture. We made some pictures, bringing in a length of the foreshore, which relieved it considerably. Two miles beyond this loch is the village of Strathyre. Nestling in the hills, it stands well for making some good studies.

If the foregoing, embracing the Leny to Strathyre, can be overtaken in one day, it certainly would be a busy day.

A Scotch Washing.

Staying at Strathyre, and going to King's House in the morning, could be done, or the other way, going back to Callander and starting back in the morning for King's House. (There was no station at King's House when we were there last, but if you tell the guard he will stop the train and let you out there.) This is the nearest railway point to Rob Roy's grave at Balquhidder. The walk to the grave is about three miles, considerably barren of trees; but there are highland huts and whins, and ferny hills and dales, all more in keeping with the wildness of the spot, and with this material there is no lack of work to do.

On a previous visit to this spot we came upon a Scotch washing, with the tubs, and bundles of clothes, and fire, and pot, with all the other paraphernalia necessary to complete a hill-side washing outfit; and the position chosen for their work was very good, behind a little one-arched bridge, with the running stream beneath. On the bank an old woman, slightly bent with age, was tending to the pot and fire, whilst a strapping lassie of twenty was stramping away at the clothes in the tub, with petticoats kilted to the knees, kicking away right lustily. We asked liberty to photograph her, and she was laughingly willing; but the old woman, who was evidently her mother, would not consent at all. She thought it was unlucky or something of that kind; but, after a little argument, we got the young one's picture—and that of the old one too, unknown to her.

After exhausting Balquhidder, when in this locality Loch Voil should be visited. It is quite near to the graves of the McGregors.

Lochearnhead.

On the return journey, about three miles from King's House, north, we come to Lochearnhead. The head of the loch is about a mile and a half from the station. This is a favoured district for artistic bits, the very high roads being cut through the most romantic of scenery. But all along the Oban line it is almost impossible to err in choosing spots crowded with natural beauties. We have Killin and the junction to Lochs Tay and Kenmore, and further on Dalmalley and Lock Awe, possessing within themselves surroundings that are almost endless in their profusion of nature's pictures.

Loch Venachar.

Coming back to Callander, we start another little trip by crossing the bridge over the Teith and turning to the right at the end of the bridge street. This is the popular walk to Loch Venachar. It is a stretch of about three miles, and well wooded the most of the way. Here we are upon ground made famous by Sir Walter Scott in his *Lady of the Lake*. The river Teith passes close to the belting of wood all the way, and the old bridge that crosses it half way to the loch makes a good picture. Behind the pretty little cottage belonging to the Water Works, close to the loch, Coilantogle Ford, is situated "Clan Alpine's outmost guard." This is the spot where Roderic Dhu challenged FitzJames to single combat. When we got there, however, we were much disappointed at the want of any prominent feature to make a picture. The light was against us certainly; but, suppose that had been right, the ford did not seem more than a weir in a dam, without any interesting surroundings except what it has gained from the poem, and we could not transfer that to a plate. The loch itself at this end is very flat and barren—the upper end improves—none of it striking, but the wooded way from the village to the loch supplies plenty of good material and opportunity for picture-making.

Returning, the village may be reached by crossing the old bridge and making a circular tour to Callander by the Trossachs road. Coilantogle Farm, and some other interesting points, will be found on this road.

WHY PHOTOGRAPHS FADE.

V.

During development or toning we can see to what extent the porous condition of the vehicle containing the silver haloids controls the results, but unfortunately in the hypo and washing baths we have not the same advantage, and, to an extent, we shall have to depend upon circumstantial evidence in our inquiry.

In fixing a print, the chloride and organic salts of silver are first converted into hyposulphite of silver, which is dissolved, as it is formed, in the excess of hyposulphite of soda present. But test-tube and other experiments teach us that if this necessary excess of hyposulphite of soda is not present *at first*, that an insoluble state of hyposulphite of silver is formed, which, when once formed, cannot afterwards be dissolved in hyposulphite of soda. In a test-tube, with sufficient silver and hypo, one can obtain the yellow and black forms of this salt, but in a print it is in such a small quantity as to be invisible until the sulphur in the atmosphere combines with it, and we then get the true yellow sulphide.

I think that here we have a clue to the cause of the deterioration of nine-tenths of our silver prints—viz., that, through the physical density of the vehicle, or on account of slight differences in manipulation, that *at first* there is not sufficient excess of hyposulphite of soda able to get at the silver chloride unreduced by light to dissolve the hyposulphite of silver as fast as it is formed, and that insoluble hyposulphite of silver is left in the film in consequence.

I have shown above how the physical condition of the vehicle affects the development and toning of the photographic image, and I have proved by sulphuretted hydrogen tests that the action of the hypo bath is governed, to a great extent, by the same conditions, so that I think we can say that it is very doubtful whether the whole of the silver can be removed from the high lights of a print which cannot be toned by the ordinary acetate or borax baths as easily and as rapidly as an ordinary albumen print, and I do not think we can depend upon a print being properly fixed if it can only be toned in a strong sulphocyanide toning bath.

We now come to the cases of the fading of prints where the physical conditions of the vehicle are identical, and yet we find that some prints stand for years without any change, others deteriorate

very soon. This difference must be due to slight changes in the method of manipulation. I do not know whether others have noticed the same, but it has seemed to me that, as a rule, small prints stand better than large ones. If it is so, it is probably due to the small prints being moved about more freely in the hypo bath at first. We will suppose a 15 × 12 print toned and washed, and laid face upwards in a 16 × 13 dish, and then the hypo bath poured over it.

On the face of the print there is an insoluble deposit of silver reduced by light plus the deposit of gold upon it. The hypo has then to get through these deposits somehow to the non-reduced silver chloride, &c., behind them. The paper is already saturated with water, which further weakens the strength of the hypo which manages to get through. Can we wonder that, in this case, there is not sufficient excess of hyposulphite of soda able to get at the chloride of silver at the back of the imago to prevent the formation of insoluble hyposulphite of silver there. Or, we will say that the hypo has been poured into the bath first—a print is put down into it, then another on the top of that, then another, and so on. In this case we get only a small amount of hypo between each print, in some places they are probably sticking together. This small amount of hypo between the prints will combine with, and be weakened by, the water in the paper, and we get the same insoluble salt of silver formed before the prints can be turned over and fresh hypo can get at the silver unreduced by light which is at the back of the image, and this is just where any combination of silver and sulphur will cause the most damage and produce fading; it is greedy for more sulphur to form a pure sulphide, which it obtains from the sulphuretted hydrogen in the atmosphere, and then the metallic silver, which is with the organic matter forming the image, begins to think it would prefer to combine with sulphur rather than the substance to which it had been previously united, and when it does that the poor photograph suffers and fades, because there is not sufficient silver present to give the requisite opacity when in the form of sulphide of silver.

It is generally acknowledged that albumen prints prepared now fade more quickly than those did which were printed twenty or thirty years ago. Can we wonder at it when we think of the much greater difficulty that the hyposulphite of soda must have to get at the silver chloride, &c., bound up in the coagulated film of the double albumenised papers?

Then, when we use papers sized with partially insoluble substances, to get a better surface image, we find even greater difficulties, because the silver unreduced by the light at the back of the image is between the insoluble image on the surface of the film and the insoluble sizing of the paper; and how can we expect a print to be properly fixed, or the hypo washed out, under such conditions, and yet some manufacturers do not seem to give a thought about such matters.

And now a word of caution as to prints on opal glass. Here all the silver dissolved by the hypo has to be got away through the image on the front somehow. I do not know where to put my hand on the results of my experiments of some years back on this subject, but if I remember right, emulsion prints on opal glass, when tested with sulphuretted hydrogen, yellowed more readily than prints with the same emulsion on paper, because, in the latter case, the hypo and silver would get through the porous paper at the back, and yet we hear people say, "Prints must be permanent if they are on glass." I also found that if prints on opal glass were stood up on end to dry, that the hyposulphite of soda and silver that the washing water could not get out of the film must have drained down through the gelatine between the image and the glass, because the lower end readily yellowed by the formation of sulphide of silver.

All this seems very simple after it is once worked out, but things of this kind cause a rare lot of work before they can be run to earth, and we must now see what lessons we can learn to apply to our everyday work.

It is very evident that the great thing required is, that the whole strength of the hypo bath must be concentrated as rapidly as possible on the chloride and organic salts of silver at the back of the image, that have not been reduced by light, so as to have sufficient excess of hyposulphite of soda getting through the paper to dissolve the hyposulphite of silver as rapidly as it is formed.

The water in the paper ought to be squeezed out of the print, or the latter ought to be put between blotting-paper before being put in the hypo bath, so that the hypo soaking into the paper is not diluted by any water already there.

There should always be an ample amount of solution in the hypo bath for the number of prints to be fixed, which must not be allowed to lay close together, but there must be plenty of room for every part of each print, both front and back, to obtain the full action of the hypo during the time it is being fixed.

I feel convinced that, when a print stands well, it has been fixed under these favourable conditions; but, if it yellows and fades rapidly, that the deterioration is due to these necessary requirements not having been carried out in a satisfactory manner.

There are some points in connexion with toning and washing of the prints that have an important bearing on their permanence, but I must leave them for a further communication.

HERBERT S. STARNES.

ADVANCED PHOTOGRAPHIC WORK FOR AMATEURS.

I.

AMONG the great army of amateurs who now practise photography as a pleasurable pastime, doubtless there will be found a large number of ladies and gentlemen who, having mastered the elementary part of photography, aim at something higher than the mere exposing of plates, with the subsequent development of same, and finally printing their own negatives by any of the commonly known methods of printing, such as the ready sensitised papers procurable from photographic dealers. To such, no doubt, a very agreeable change will be found by giving some little thought and attention to opal work. By this I do not mean the use of the common form of gelatino-bromide opals, which are advertised in nearly all photographic periodicals, and which necessitate development after exposure by contact or through the camera, but the more easily manipulated and cleanly, good old form of printing-out opals, whereby most beautiful results may be obtained by merely placing a sensitised opal in contact with a suitable negative in a printing frame, in exactly the same manner as they would a piece of sensitised silver paper.

Such method of printing is by no means so well or largely adopted as it might be, doubtless on account of the inability of amateurs and others to get a supply of such opals ready sensitised from the various dealers, like they obtain other requirements. Still, to any one desirous of departing from the beaten track, and striking out into fresh pastures, there is really no trouble or any reason whereby such should not, with the greatest certainty of success, prepare their own emulsion, and coat and dry their own opals.

Kind reader, at the outset do not let me frighten you away from this delightful method of printing by the mere mention of any one making their own emulsion and coating their own plates. Do not conjure up visions of grovelling in dark rooms, with its attendant tedious boiling operations, and all the other bugbears in its train. Such is not required in the production of the emulsion I am dealing with; whilst to those who are inclined to undertake something they have never previously attempted in photography, I can safely say, once they experience the delight of making their own emulsion and preparing their own sensitised opals, they will never regret having taken such a departure, for very likely it will open their eyes to see and understand much that in the past was quite beyond their ken.

Let any one, therefore, so inclined, and who having beside them a stock of spoiled opals, proceed without delay to wash off the gelatino-bromide films. This is best done by making a saturated solution of washing soda, into which place the opals for, say, twenty-four hours; then take a flannel pad, and, having obtained from the kitchen-maid her Bath-brick, proceed to rub off the old emulsion. Powdered Bath-brick is the best thing I know of for cleaning soiled opals; it is far and away ahead of powdered pumice-stone. Having got a supply of clean opals, let them be stowed away until a small quantity of emulsion be made, an operation which takes less time to perform than it takes me to write particulars about. Within recent times the cost of opals has fallen very much in price, and those not having any soiled ones can at a very trifling cost procure a supply from any photographic dealer, and they can be had either with matt or glazed surfaces. The former, I would suggest, should be used by any one who for the first time undertakes this work; but of this I shall speak more fully when I come to refer to the coating of the plates. Now as to cost. Surely a modest sixpence is not an extravagant sum for any one to expend in amateur emulsion-making, yet for this small outlay sufficient emulsion can be made to coat two dozen half-plates.

Then, as to facilities of making emulsion and drying of the coated plates. The whole operation can be performed without any mess at an ordinary kitchen fire, or on a parlour table, provided the operator has the luxury of a good Fletcher gas-stove.

Begin working in ordinary gaslight by getting the cook to provide you with a clean jam pot, into which place two ounces of clean cold water. Then add to, and dissolve in the water, six grains acetate of soda, after which add forty grains hard gelatine. Place the jam pot in a saucepan of water, and warm the water in the saucepan up to 100° Fahr., not more; the gelatine in the jam pot will soon be melted. Now, having obtained from any chemist or elsewhere

thirty grains of nitrate of silver (it will cost threepence), place same in a glass measure, and dissolve the silver in one ounce of clean cold water, add this to the melted gelatine in the jam pot with vigorous stirring. Next, place in a clean glass measure, or other suitable vessel, two ounces clean cold water, into which place eight grains acetate of soda, and four grains chloride of ammonium, dissolve, and with vigorous stirring add the same to the melted gelatine in the jam pot. Keep the water in the saucepan gently warmed, not over 100° Fahr., at no stage should it exceed this. A stem thermometer will easily enable an operator to keep the water in the saucepan at the proper temperature. Next, take 160 grains hard gelatine, and soak the same till softened in clear cold water, then pour off all the unabsorbed water, and add the gelatine to the emulsion in the jam pot. Stir well with a glass rod till all the gelatine is melted, then cover over the jam pot with a clean cloth, tied over the top, and set aside in any dark cupboard, or old hat box for twenty-four hours—or say till next evening—when, on examination, the jam pot will be found to contain a jelly-like mass; the pot is now again placed in a saucepan of warm water, not over 100° Fahr., till melted, and having provided another clean jam pot, over the top of which a clean handkerchief has been stretched, damp the same with clean warm water, but do not run any water into the jam pot. When the jelly-like mass of emulsion is melted, add half ounce alcohol—or methylated spirit will do—and pour the emulsion through the handkerchief into the clean jam pot; this, if done properly, will filter the emulsion quite well enough for the class of work we are considering. Finally, add two ounces of clean cold water, and the emulsion is complete, and the same may be at this stage used for coating the plates, or it may be set aside in a dark box for use at any future time. When, say, it is desired to coat only an odd plate or so, it is best to take out with the fingers, or a horn spoon, just sufficient of the jelly-like mass of emulsion when it is cold, and only heat as much as is about necessary to coat the number of plates required. This can be easily done by placing the lump of emulsion broken off from the mass in a clean tumbler, and by placing the tumbler in a pan of warm water, melt it, and keep it at an even temperature, with water not above 100° Fahr., during the coating of plates. This method saves the too frequent melting of the entire pellicle of emulsion when only a small quantity of plates are needed.

T. N. Armstrong.

PHOTOGRAPHIC SURVEY OF WARWICKSHIRE.

The formal presentation, of the photographs which have been taken by members of the Birmingham Photographic Society in prosecution of the scheme for a photographic survey of Warwickshire, to the Mayor for safe custody on behalf of the citizens, was made on Saturday afternoon at the Art Gallery, where the survey pictures are now on exhibition. The presentation was made by Mr. J. B. Stone, as President of the Birmingham Photographic Society, and, in addition to the Mayor, there were present Alderman Johnson (Chairman of the Free Libraries Committee), and Messrs. J. Satchell Hopkins, S. H. Baker, H. S. Pearson, Joseph Hill, John Collier, Whitworth Wallis, A. B. Chamberlain, and several of the gentlemen who have contributed to the collection.

Mr. J. B. Stone said the undertaking in which they had engaged was one of enormous difficulty and magnitude, and, although already over 1000 excellent pictures had been sent in, they formed only the mere fringe of the whole scheme they had in view. They hoped that it would eventually embrace, not only the architectural and antiquarian aspects of the county, but also its botanical and geological aspects, and also copies of the portraits of Warwickshire worthies which were hanging on the walls of many ancient buildings of the county, or were otherwise obtainable. The Society desired that their contributions should not be regarded as in any way examples of photographic art, but purely as historical records. The work had been warmly taken up by the members of the Society, and they hoped in the future to have the assistance of many other Photographic Societies in the county, and that for several years to come they would be able to add annually to the collection which they were now inaugurating, and which they left confidently to the safe keeping of the Mayor and Free Libraries Committee.

The Mayor said if Science had provided the means, and the inhabitants of the city and county had had an opportunity of making records of what existed in past generations, it would now have been of the utmost value to Birmingham and the county at large, and, by deduction, they themselves knew how great the value would be to the future of what they had done and intended to do. It was a source peculiarly pleasant that this gift should have been made to the city through the hands of Mr. J. B. Stone, whose interest in photography, and desire to do that which he had now accomplished, they all knew.

The collection, which consists of some 500 photographs, represents about one half of the work done during 1891 in connexion with the survey, and some fifths of the exhibits have been contributed by members of the Local Society, some few having been sent in by the archæological section of the Midland Institute, and some others by outsiders. The photographic element of Coventry, Leamington, Rugby, and Wylde Green, together with the Arden Club, of Solihull, were asked to assist, but did nothing. The exhibits, which are all printed on platinotype paper, and from whole, half, and quarter plate negatives, have been prepared on a truly scientific and systematic basis. On the back of each is written a quantity of detail as to the object itself, and the conditions under which it was photographed, which will be of inestimable value to the archæologist, and would enable an architect to reconstruct the original if it disappeared. The work of surveying was last year done rather casually, but this will not be the case in 1892. The Council have mapped out sections of a square mile each on the ordnance map, and allotted them to one or more members, with advice to special individuals to adhere to special sorts of work. They supply a list of the most suitable objects to be taken, and issue special permits for the workers. Under all circumstances it is not surprising to learn that the survey may take some years to complete. Mr. Whitworth Wallis has prepared an excellent catalogue, for which Mr. Jethro Cossins and Mr. James Simkins have written historical and architectural notes.

In the evening the Council of the Survey, on the invitation of Mr. J. B. Stone, met the Mayor at dinner at the "Colonnade Hotel," in celebration of the presentation of the first instalment of the photographic records. Among the guests were Messrs. J. H. Stone, Jonathan Pratt, Alfred Hayes, J. Simkins, J. A. Bagnall, J. F. Mousley, F. G. Lyndon, W. J. Harrison, Whitworth Wallis, E. H. Jaques, W. Roche, W. Buncher, Joseph Hill, H. Baker, E. H. Leeson, J. H. Pickard, W. S. Horton, John Collier, E. W. Badger, A. R. Longmore, W. Jones, E. C. Middleton, &c.

Mr. Joseph Hill proposed "The Warwickshire Photographic Survey," and said there could be no more agreeable task than that on which those taking part in the Survey had entered. The Archæological Section of the Birmingham and Midland Institute had done most valuable work in the past in the series of photographs taken for them by Mr. Collier of subjects which it would now be impossible for them to obtain. But there was very much more to do than this Section could possibly undertake, and the Survey was exactly the thing wanted. They were deeply indebted to Mr. Jerome Harrison for having suggested it.

Mr. Jerome Harrison replied to the toast, and said, though the honour had been claimed for him of having broached the idea of the Survey, its practical accomplishment was almost entirely due to Mr. Stone, and the success which had been achieved in Warwickshire would render similar work in other parts of England much easier than would have otherwise been the case. Already a dozen or more Photographic Societies in other parts of the country had copied their example, and they hoped before long to see the whole of the 300 Photographic Societies in the country engaged in the work.

Mr. J. H. Pickard (Hon. Secretary to the Survey Council) and Mr. Simkins also briefly acknowledged the toast, and the former prophesied that the next annual collection would show a great advance on that now being exhibited. The latter said the present exhibition consisted really of desultory work, but very shortly the Organizing Committee of the Survey would issue their prospectus for the next year's work, and it was hoped that more systematic and concentrated effort would result.

Our Editorial Table.

The First Principles of Photography.

By Clement J. Leaper.

This work is an elementary treatise on the scientific principles upon which practical photography depends, and embodies in it the substance of the courses of lectures on photography annually delivered by Mr. Leaper since 1882 at the Dublin Mechanics' Institute and City of Dublin Technical Schools. It would be extremely difficult to discover any topic connected with photography which Mr. Leaper in these thirty-five lectures has neglected to touch, and to treat in a thorough and facile manner. It contains 260 pages with numerous illustrations. Published by Iliffe & Son, St. Bride-street. Price 5s..

Practical Enlarging.

By John A. Hodges, Vice-President of the West London Photographic Society.

In this manual, also published by Iliffe & Son (price 1s.), Mr. Hodges discourses in a practical manner on the various methods of making enlargements as practised at the present time. He also gives directions concerning the production of enlarged negatives. He expresses the opinion that an enlargement produced from a small negative must necessarily be superior to a print from a large negative taken direct, on account of the greater depth of definition given by a small lens of short focus. Eighty-seven pages.

The "Imperial" Plates.

The Imperial Dry Plate Company, Cricklewood.

Some samples of this new brand of plates (of the Extra Rapid kind) which we have recently tried yielded us exceedingly bright

and vigorous negatives. From a technical point of view the plates appear to be excellent. It is an additional point in their favour that they are amenable to the action of the chief ordinary developers in common use.

The Pocket Changing Bag and Focussing Cloth.

By W. R. Baker, Wallington, Surrey.

In this Pocket Changing Bag Mr. Baker has made several improvements upon the one intrdouced by him in July last year. The bag is formed of a soft pliant material, lined with a flexible red fabric, both of them of such close texture as to prevent admission of light. The window in front (shown in the cut) is so constructed that the

amount of light can be regulated. While small enough to go into one's pocket, it is so expansive when opened as to permit plates up to whole-plate size to be changed. A species of domino mask held close to the eyes by elastic bands prevents light from getting to the interior. The sleeves are also light-proof. It is a cheap seven-and-sixpennyworth.

The Strand Magazine for May.

If we except the rather namby-pamby photographs of "May Queens," the illustrations in the May number of the *Strand Magazine* are excellent. This is especially the case with those of Sir John Lubbock's article, "Beauty in Nature," and "Adventures of Sherlock Holmes." The "Portraits of Celebrities" in this number consist of Madame Mary Davies, Walter Besant, James Rice, Marcus Stone, R.A., Alphonse Daudet, Lionel Brough, and Henry W. Lucy ("Toby, M.P."). These, as usual, are well executed, and show the various subjects at intervals from youth up to the present period.

Received :—*A Short and Easy Road to Photography*. By Charles W. Brumwell. The "easy road" is indicated in half a dozen pages, the remainder of the pamphlet being devoted to a price list.—*My Camera and How to Use it*. By W. Scorer. This is also a brief pamphlet, treating of the subject in clear and easily understandable language.

PATENTS COMPLETED.

Method of and Apparatus for Reproducing Photographs.

No. 7785. Bernard Krantz and Hermann Zeissler, 13, Bunhill-row, City of London.—*April* 9, 1892.

This invention has for its object the reproduction of photographic pictures in ink at a small cost.

According to this invention we take from nature or from pictures or prints a negative either in the usual way, or with a "Raster" or grained plate interposed between the lens and the sensitive plate.

A transfer print is made from the negative by any of the well-known methods. We then take a piece of calico and spread on one side thereof a film of sensitive gelatine. We transfer the print to the gelatine (by exposure to light) and high etch the latter by means of glycerine and liquid ammonia, thus producing what we call the calico and gelatine block.

When finished the calico and gelatine block is mounted on a piece of wood or metal provided with a handle, to enable it to be used as a hand stamp, and then prints or impressions can be taken from it in the usual way.

Improved Method of Photo-etching on Zinc and Copper.

No. 8121. Bernard Krantz and Hermann Zeissler, 13, Bunhill-row, City of London.—*April* 9, 1892.

The object of this invention is to produce, by means of photo-etching on zinc and copper plates, suitable for producing in "half-tone," the highest class of printed work, such plates being prepared ready for printing from in less time and at a smaller cost than any plates of whatever description now used for printing from.

According to our invention, we take a tin plate of suitable size and shape, and cover the same with a coat of lampblack, and when this is dry, we coat over the lampblack with Chinese white, and thoroughly dry the plate. We then, by means of an ordinary ruling machine, rule on the prepared plate, through the white only, diagonal, horizontal, vertical, or crossed, straight, waved, or jagged lines. This operation leaves the plate showing black lines on a white ground. We then throw an enlarged image of the picture or design to be printed on the ruled plate by means of a magic lantern. We then take a negative of the dimensions of the finished print by means of a photographic camera in the usual way from the picture or design as thrown on the tin plate by a magic lantern, and print from such negative on the zinc or copper plate, which has been previously sensitised with bitumen, and develop the picture on the zinc or copper by the aid of turpentine in the usual way. If the plate used is of zinc, we next immerse it for about thirty-five minutes in a bath of three parts nitric acid and twenty parts water by measure. When removed from the bath, we sponge off all the acidulated water with a solution of gum arabic and water. The deep shadows will now be well visible. We next immerse the plate for about five minutes in a saturated solution of carbonate of soda, and then place it under running water for a short time, and lightly rub it with a soft rag or brush for the purpose of cleaning the picture from any deposit of nitrate of zinc. When the plate is sufficiently washed, we ink it with ordinary printer's ink, and dust it well with powdered resin; the loose powder is blown off, and the plate again immersed in the acid bath, and, after allowing it to remain therein for about an hour, we remove it therefrom, and wash it well with oil of turpentine. We next ink the plate with etching ink, composed of equal parts of paraffin wax, tallow, and printer's ink, and replace it in the etching bath for about thirty-five minutes.

To accelerate the etching process, we may add to the bath for the two last etchings, a little at a time, a small quantity of both sulphuric and hydrochloric acids, the quantity to be in proportion to the hardness of the plate. When sufficiently etched, the plate is mounted on wood, and is then ready for printing from. If the plate to be prepared for printing from consists of copper instead of zinc, we for the first two etchings substitute for the nitric acid an equal quantity of a saturated solution of perchloride of iron in the etching bath above described, the bath for the third etching being the same as hereinbefore described for zinc plates. Or, instead of photographing an enlarged picture on to the ruled plate, as hereinbefore described, we may take a photographic negative direct from the picture, drawing, or object to be reproduced, and another negative (wet plate) from the ruled plate. These negatives we place in a magic lantern, with the negative from the ruled plate in front, and throw the combined image from both negatives for a sufficient time direct on to the zinc or copper plate, which has previously been sensitised with bitumen. After the picture has been developed on the plate by turpentine, the plate then etched and prepared as hereinbefore described. This process is also sui

able for preparing zinc or copper matrices for making indiarubber stamps, and for engraving zinc or copper seals or dies in intaglio or relief; but when engraving in relief is required, a positive photograph must be used instead of a negative.

Having now particularly described and ascertained the nature of the said invention, and in what manner the same is to be performed, we hereby declare that what we claim is:—1. In the process of photo-etching on zinc and copper, the taking of a photograph from a picture or design thrown by a magic lantern on to a ruled plate, as and for the purpose hereinbefore stated. 2. In the process of photo-etching on zinc and copper, the throwing by a magic lantern of the combined image from two negatives on a zinc or copper plate sensitised with bitumen, substantially as described. 3. The improved process of photo-etching on zinc and copper, substantially as herein described.

Improvements in Apparatus for Photographing Engineering Drawings and the like.

No. 9591. William Palmer, 1, Greenvale-terrace, Dumbarton, Dumbartonshire, North Britain.—*April* 9, 1892.

My said invention has for its object to obtain increased efficiency, convenience, and economy, in photographing engineering drawings and the like; and it is applicable for making white-ground, blue-ground, or other analogous prints.

In carrying out my invention I employ, for the printing operation, a frame having a glass plate, which is curved instead of being of the ordinary flat form, and I secure the tracing or original, and the photographic paper on the convex surface of the glass plate by means of straps, or a cloth which can be highly stretched or bound over them, the arrangement being such as to allow of the tracing and paper being made free from creases, and applied very closely to the glass. In general, the frame may be placed so that the light will act on the concave side, through the glass; in some cases, however, the photographic paper may be placed next to the glass, and the tracing upon the paper, the light acting through the tracing, and on the convex side, instead of the concave side.

For developing the print I form it into a roll, and attach it to a rod, or convenient holder, and immerse it in the chemical liquid contained in a tall vessel of glass, or other suitable material, of a circular or other simple form in horizontal section. The said vessel is proportioned to contain a quantity of the chemical liquid just about sufficient for the operation on the print without unnecessary excess. Where drawings of various sizes have to be photographed, vessels of suitable sizes may be provided. With these arrangements, a smaller quantity of chemical liquid is required for each operation than with ordinary apparatus for the same purpose, this being an important advantage, especially for white-ground prints, for which the chemical liquid should always be as fresh as possible.

Improvements in the Methods of Producing Two or More Coloured Prints.

No. 6634. Eugene Albert, Schwabing, near Munich, Germany.—*April* 16, 1892.

This invention relates to the methods of making two or more coloured prints from colour plates or stones, and of photographically producing autotypic colour blocks or stones, and has for its purpose to attain more perfect results than heretofore.

When making a double print from an autotypic block in black colour, either the double prints differ only by greater intensity of colour from the simple prints, that is to say, the lines or grains coincide in the second printing precisely with those first printed; or the lights of the double prints appear grey, and the deep shades, disturbed by the two consecutive printings, have undergone a parallel displacement relatively to each other; or in large quiet surfaces dark stripes are observable, which vary considerably in distance from each other. The latter irregularity is produced by a slight turning of the two printings relatively to each other. The lines, therefore, cross each other at interstices, which are the smaller the greater the said turning has been. At the crossing points the lines lie upon one another, at all other points beside one another. Two lines lying upon each other appear lighter than two lines lying beside each other. The more acute the angle under which the lines cross each other, the more extended is that part where the lines lie upon and cover each other, that is to say, the larger become the light interstices between the dark stripes. When said angle becomes infinitely acute, the interstice becomes infinitely large; no stripes are formed, and the prints coincide absolutely. This latter result is, however, in general, very seldom attained, owing to the influence of the temperature on the paper, and by other reasons. That a very slight displacement or turning suffices to produce the said irregularities, may be gathered from the fact that autotypic blocks generally have five to seven lines to the millimetre, and that consequently the interstice between the lines amounts to about one-tenth to one-fourteenth of a millimetre.

The above applies naturally also, and in a greater measure, to the consecutive printing with several blocks which correspond to different colours, especially if they have been produced by photography.

When printing consecutively with several blocks in different colours, the prints again either happen to fit exactly, or a displacement or turning takes place. If the prints fit precisely, certain rays are absorbed, and only those colour rays which are common to two coinciding colours appear as the result of mixture, *i.e.*, pigment mixture is produced. If, however, the prints are parallelly displaced, the rays proceeding from adjoining points are only united in the eye of the observer, *i.e.*, optical mixture takes place, which has results differing from those of pigment mixture. If the prints have been turned relatively to each other, we have pigment mixture at the covering or crossing points, and optic mixture at all other places, whereby stripes of different lightness, as well as such of different colours, are produced, which, with printing in different colours, frequently result in most peculiar patterns. This formation of patterns, which renders coloured printing from line-plate blocks impossible, is entirely obviated by the application of line-plate systems which are inclined under a certain angle relatively to each other.

As mentioned above, the more acute the angle formed by the crossing of the lines, the more extended is that part along which the lines cover one another. It is evident that this part becomes shorter in proportion to the increase of said angle. Said part, with a crossing angle of thirty degrees, is so much shortened that no more stripes are formed. As with autotype printing, a line-plate system consists of two relatively vertical lines, each system must be turned for sixty degrees for printing three colours upon each other by means of autotypic blocks. With two colours, the above crossing angle may vary between thirty and sixty degrees. Also the other drawback, viz., that the colours are mixed either optically or as pigment, is obviated by the improved method, the lines being compelled through the large angles to cross each other at small intervals, whereby optic and pigment mixture is always produced simultaneously.

Meetings of Societies.

MEETINGS OF SOCIETIES FOR NEXT WEEK.

Date of Meeting.	Name of Society.	Place of Meeting.
May 23	Dundee Amateur	Asso. Studio, Nethergate, Dundee
,, 23	Gloucestershire	
,, 23	North Middlesex	Jubilee Hall, Hornsey-road.
,, 24	Great Britain (Technical)	50, Great Russell-st., Bloomsbury.
,, 25	Bath	Roy. Lit. & Sc. Inst., Terrace-walks.
,, 25	Burnley	Bank Chambers, Hargreaves-street.
,, 25	Photographic Club	Anderton's Hotel, Fleet-street, E.C.
,, 26	Birmingham	Lecture Room, Midland Institute.
,, 26	Camera Club	Charing-cross-road, W.C.
,, 26	Hackney	Morley Hall, Triangle, Hackney.
,, 26	Halifax Photo. Club	Mechanics' Hall, Halifax.
,, 26	Hull	Royal Institution, Hull.
,, 26	Ireland	Rooms, 15, Dawson-street, Dublin.

PHOTOGRAPHIC SOCIETY OF GREAT BRITAIN.

May 17,—Mr. W. E. Debenham in the chair.

Photogravure.

Mr. A. Dawson read a paper on *Photogravure*, chiefly dealing with the subject in its economic, practical, and artistic aspects. In his introductory remarks he said that it was quite impossible for one man to master all the details of modern photography. In the progress of any particular branch one could never learn or practise too many of the details. Modern workers were largely indebted to the efforts of the late Robert Hunt. The copper-plate process was of many years' standing, but the cost of the plate was fixed, and it was now only a question of the greater or less ease with which the plate could be printed. The lights of the old mezzotint were more beautiful than process plates, because there was more clean paper in a mezzotint, but the latter was more expensive to print. Photogravure cost a penny per impression for labour only, and this, added to the cost of a plate, say, 4*l.*, made it necessary for several thousand prints to be made before the cost of production yielded a profit. A number of subjects on one plate gave an economical method of printing, and separated prints could be made before a book was ready. If printed on thin paper, the latter had to be backed up with a thick paper. For mounting, labour was cheap. Collotype gave some idea of copper work, especially if printed on thick paper without any gloss. He was surprised that photogravure was not taken greater advantage of in work for presentation plates. Discussing the artistic aspect he thought the artist's ideas should always be consulted. In the ideal photogravure the touch as well as transparency should be preserved. He complained of the narrowness of the photographic scale as given by negatives, and regretted that he should have to make parts of his lights and shadows artificially. There was a physical resemblance between photogravure and many of the little plates found in modern illustrated books, the latter simply being photogravures in negative. Treating of other processes, he said hand work was generally apparent, and in photogravure this would not do. He had often been asked as to the possibility of printing from a coloured plate. Martin's method was probably the best. In this, parts of the plate were coloured, and then scraped away as required, the printing being done in careful register. Three or four printings were necessary, but the registration was difficult. He did not see his way to making a plate in "nature's colours," as the plate mark would have to be cut away. He concluded by enumerating ten photogravure processes, by Waterhouse, Klic, Niepce, and others. Waterhouse had obtained a grain by means of ground glass. He (Mr. Dawson) had added a little stearine to sand, and had also inked over the tissue with tallow and oil, and bronze powder. He had also resensitised the exposed bichromated film, developed the picture, greased it, and applied bronze powder and printed in the daylight. In the Goupil method, the film was like a sponge on the plate. He was sorry that this process, which was a secret one and due to the late W. B. Woodbury, should have been allowed to leave the country.

Mr. T. Bolas agreed with a remark of the Chairman's that the lecture was a most interesting one, and thought it justified a few more details from Mr. Dawson.

The Chairman said that Mr. F. E. Ives had that day, at the Royal Institution, indicated the kind of colours that must be used for inking plates, and had shown results. The colours were not the old primaries, nor those which were now recognised as primaries, red, green, and violet-blue, but their complementaries, yellow, a sort of lilac, and blue-green. Thus a negative

taken through a red glass would be printed with the colour complementary to the red. He was sorry to hear that Mr. Dawson had to make his lights artificially, and hoped for the time when photography would do its work throughout. Drawing attention to the examples of photogravure on the walls, he said the process had been practised more completely in Germany, though doubtless Goupil's work was better known, on account of the subjects reproduced. There was a large amount of hand work in them. There were often fine examples of photogravure in the German periodicals, having a depth in the shadows not often seen in matt prints. He suggested study of the German works on the subject.

Mr. E. CLIFTON suggested that it would be a good thing for the Society to start a representative historical collection of prints. They had often wished to possess such a collection. It should be produced by a process free from the charge of evanescence. It would add to the importance of that Society, and the collection should be a national record of photographic history and progress.

A vote of thanks having been passed to Mr. Dawson, the meeting closed.

LONDON AND PROVINCIAL PHOTOGRAPHIC ASSOCIATION.

MAY 12,—Mr. A. L. Henderson in the chair.

AMATEUR AND PROFESSIONAL.

Mr. A. HADDON referred to recent demonstrations and papers on the wet collodion process given before the members, and suggested that amateurs should make wet collodion positives instead of gelatine negatives, and thus remove the slur which professionals cast upon them, of interfering with professional photography. Mr. A. Haddon further mentioned that the Committee of the Association had arranged for a series of lectures to be given before the members which would afterwards be produced in book form. Promises had been received from Mr. J. Traill Taylor (who would discourse on *The History of Photography*), Mr. W. E. Debenham (*On Lenses*), Mr. A. Cowan (*Cameras*), Mr. A. L. Henderson, and others.

Mr. A. MACKIE asked if Mr. Haddon was serious in suggesting that amateurs should go back to positives? When they made wet-collodion negatives, prints were wanted from them just as they were from gelatine negatives now.

Mr. W. E. DEBENHAM said wet collodion positives were capable of giving better delineation than prints obtained in the ordinary way, and did not afford the same facilities for spoiling by retouching. Professionals should hold themselves above the paltry consideration of amateurs taking the bread out of their mouths. If amateurs' work was better than professionals', why, then the professionals must suffer.

Mr. F. A. BRIDGE mentioned that the photographing of [engineering] work had largely gone from photographers, many firms now getting it done at nominal cost by their relatives or *employés*.

Mr. P. EVERETT asked if a professional photographer had any prescriptive right in such matters? It seemed to be looked upon as a grievance that he did not get so many orders as hitherto.

Mr. MACKIE said that probably so many people knew the prices of photographs now that they would not buy them. The ordinary professional photographer was a very narrow-minded man, who, with the chemist, always thought he must have a monopoly.

Mr. W. G. BLACKIE, of the Blackfriars Photographic Company, exhibited and described the Anschütz Instantaneous Camera, and also a number of pictures of animals, &c., taken with it. Mr. Blackie subsequently passed round a collection of celerotype prints from negatives by Mr. Hudson.

QUESTIONS.

The following question from the box was asked: "How can you ascertain when the fixation of a silver print is complete?"

The CHAIRMAN suggested using the hypo pretty strong and giving the print plenty of time.

Mr. MACKIE said that then the print would not necessarily be properly fixed, and Mr. HADDON described the chemical changes produced in fixation.

Mr. FOULKS-WINKS suggested a second fixing bath, and testing it for silver.

Mr. S. J. BECKETT said that the question had been put at a recent City Guilds' Institute examination.

Mr. T. BOLAS suggested that the examiner be written to, asking him to tell them, for the benefit of photography, how to ascertain when the fixation of a silver print is complete? Having put the question, the examiner (Mr. Lyonel Clark) would no doubt be able to answer it.

Mr. Bolas's suggestion was agreed to.

Another question was, "What is the best means of cutting opal glass?"

Mr. A. COWAN suggested an old diamond, and Mr. G. W. ATKENS a wheel cutter, which stands more pressure than the diamond.

Mr. J. E. SMITH wished to know whether, as it was recommended to let a mixed gold and acetate bath stand for twenty-four hours, the gold and soda, if mixed separately, could not be used at once. The answer given was, No.

A third question asked a rule for calculating the exposure of an enlargement to a given size with a lens of a given size.

Mr. DEBENHAM said: Take the number of times that the length of the original is contained in the length of the image, add 1 and square the sum. Thus, in copying to the same size, the length of the original is contained once in the original 1, add 1=2, squared =4. For twice the size of the original, the result would =9, and thus a picture copied double the original size would require two and a quarter times the exposure of a picture copied same size with the same lens and stop. Mr. Debenham also said the rule was applicable to reductions as well as to enlargements.

TELEO-PHOTOGRAPHY.

Mr. H. M. HASTINGS had used a negative eyepiece in conjunction with a rectilinear lens, as recently suggested by Mr. J. Traill Taylor, and had tried the combination on the eclipse of the moon at a quarter to twelve the previous night. With an exposure of fifteen seconds there was considerable movement of the image. Reduced to three seconds, however, the remaining exposures were correct. The rectilinear lens was fourteen inches in focus, the draw of the camera being nineteen inches. What was the focus of the combination? Unfortunately he had used a nonachromatic eyepiece. Mr. Hastings showed several pictures of the eclipse, as also views of a house at 400 yards distance with an ordinary and a tele-photo lens respectively, the camera in the latter case being drawn out to sixteen inches.

MR. F. E. IVES.

Mr. BOLAS adverted to the work of Mr. F. E. Ives, which he said he had studied carefully, and said that he considered it a real advance. It was surprising how one saw photographs in colours in their true relation in the examples shown by Mr. Ives.

It was decided to invite Mr. Ives to lecture before the Association on the subject, and Messrs. T. R. Dallmeyer and J. Traill Taylor to lecture on teleo-photography.

Hackney Photographic Society.—May 12, Annual General Meeting, the President (Dr. Roland Smith) in the chair.—A satisfactory report was read by the Hon. Secretary, and the Treasurer reported 15*l.* in hand to carry over to the next season. The following officers were then elected:—*President:* Mr. Herbert Robertson.—*Council:* Messrs. W. L. Barker, R. Beckett, F. W. Gosling, F. Houghton, W. P. Dando, and Dr. Roland Smith.—*Curator:* Mr. Arthur Dean.—*Treasurer:* J. O. Grant.—*Hon. Secretary:* Mr. W. Fenton Jones, F.S.Sc., 12, King Edward-road, N.E. The night of meeting was changed to Tuesday, and also will, after June, be every week. The entrance fees remain as before. It was also agreed that the Club quarters be changed to a place of more social character, and premises have been secured where all the advantages of club life can be had. The Society has ninety active members, and promises well for the future. During the past season papers, &c., have been given by, amongst others, Messrs. T. C. Hepworth, A. L. Henderson, Henry Sturmey, Mackie, Foulks-Winks, Sinclair, &c. A most successful exhibition was held last October, when Captain Abney presented the prizes to the successful exhibitors.

Kensington and Bayswater Photographic Society.—May 9, Mr. Frogbrook in the chair.—Five questions from the question-box were read and discussed. Two of these seemed to give some difficulty in answering. They were as follows:—1. I have found fifteen seconds at one foot from a certain light to be the correct exposure for making a lantern slide by contact from a certain negative. What will be the correct exposure for making a lantern slide by reduction, using the same negative and light, the stop used being *f*-16, the negative being placed three feet from the lantern plate? 2. The above gaslight exposure being known for contact work, can the correct exposure for daylight be ascertained in any way from it? Mr. JONES gave a demonstration on *Photo-micrography*, showing some excellent microscopic slides and the lantern transparencies produced from them. He also showed with his instruments the best way of fixing the microscope and camera together.

Richmond Camera Club.—Friday, the 6th, was an extra Lantern Night. Slides were shown by Messrs. Kelsey (chiefly boat-race shots), Davis, and Ardaseer, and a fine selection of professionals' slides, lent by Messrs. Dick, Hunter, and Alabaster.

South London Photographic Society.—May 2, Mr. A. G. Banks (Vice-President) in the chair.—The Autotype Company's representatives (Messrs. Brown and Burton) attended to demonstrate the working of the carbon process. After giving a short history of the process, they explained the means by which the issues and temporary supports were prepared, and the method of printing. They proceeded to develop a large number of prints, both on single and double transfer tissue, in various colours. The means by which prints were completed were then dealt with. A large number of finished prints and transparencies were exhibited in the room. There was a large attendance of members (fifty), many of whom showed themselves to be very much interested in the working of the process, and seemed surprised at the simplicity and ease by which good results could be obtained by it. It was announced that Mr. Kirby had contributed a number of scarce photographic works to the Society's library.

Croydon Camera Club.—May 9.—Mr. E. J. WALL delivered his lecture on *Development*. The discourse proved to be mainly directed to a repetition of the assertion that the printing character of the negative cannot be influenced by the system of applying the developer. In order to prove his thesis, Mr. Wall exhibited a number of negatives which had been exposed on graduated squares, the series of squares being numbered from one to twenty-four, No. 1 being the extreme white, and No. 24 the extreme dark. A large number of plates were exposed in succession before this series for sixty seconds each, the illuminant (a paraffin light) being kept as constant as possible, and the distance being in each case the same. In every instance the development was carried to "fogging point." It is here impossible to tabulate all the many experiments which the lecturer described in modifying the proportions of the various ingredients in developers operated with; but his illustrations were mostly in some such form as follows:—First series. Plate (1) developed with, per ounce, 2½ grains pyro, 2½ grains bromide, 2 minims ammonia. (2) Same, but double the bromide. (3.) Without bromide. The resulting negatives were certainly more in accord with the popular notion than with the theories of Messrs. Hurter & Driffield. Series 2 illustrated the effect of altering the proportions of pyro. Series 3, of altering the proportions of ammonia. Eikonogen and hydroquinone were also similarly treated. At the end of an unusually interesting and suggestive paper a lively discussion ensued on development in general. Mr. D. E. GODDARD advocated the oxalate developer for all work except where considerable under-exposure is suspected; even then, by using a small proportion of hyposulphite with the developer, detail may be brought out. Mr. C. F. OAKLEY favoured rodinal being given a trial, he having obtained good results by using a strong solution (one to fifteen) for snap-shot work. Mr. J. PACKHAM mentioned that a variation in Beach's developer, by adding a small portion of ammonia in place of part of the other alkalies used in the solution, was very promising. In the discussion it was the general opinion that Mr. Wall had proved his case. On May 14 Mr. S. E. Burrows conducts a party of members to Mitcham; train leaves West Croydon at half-

past two. On May 21 the President (Mr. Maclean) conducts members to Nutfield; train from East Croydon at forty-seven minutes past two. May 23, Lantern Night; members' slides.

Birkenhead Photographic Association.—The meeting opened by passing a vote of condolence to the family of the late member, Mr. John Hartnup, the astronomer, who was killed by a fall off his observatory at Bidston last month. Mr. John N. Welch gave a demonstration of the new Ilford printing-out paper, and passed round an album showing the results he obtained with it. Mr. Lange and other members passed some of their slides through the lantern.

Bolton Photographic Society.—May 3, Mr. William Banks in the chair.—Messrs. J. T. Cooper and W. Abbott were elected members of the Society. Mr. C. K. DALTON read a paper on the *History of the Stereoscope*, and many stereoscopic transparencies and slides were exhibited by Messrs. A. Knowles, J. Young, A. Harper, J. E. Austwick, and others, a number of the slides being from negatives taken at the Society's recent visit to Miller's Dale. Messrs. R. and J. Beck exhibited a mirror stereoscope, and Messrs. Husbands, Bristol, one of Harding Warner's panorama stereoscopes, and Mr. Young a complete set of apparatus for producing stereoscopic transparencies.

Derby Photographic Society.—May 7, First Outdoor Meeting.—Fifteen members were present, leaving Derby by the thirty-eight minutes past one train in two compartments kindly reserved by the Midland Railway Company. They soon arrived at Kegworth, rather astonishing the good people at this place by the large array of cameras, tripods, &c. A pleasant walk of a mile and a half brought them to the very quaint village of Lockington. Cameras were soon unpacked, and a number of pretty views taken. They next wended their way to Hemington, which appeared to be more particularly noted for its ruined church, founded A.D. 1450; journeying forward to Castle Donington, where several more views were taken. A group of the members present was taken by Mr. Lowe. Altogether forty-two plates were exposed. Derby was reached at eight p.m. Mr. A. B. Bennett officiated as leader.

Southport Social Photographic Club.—The usual monthly social was held at Mr. Cross's studio, 15, Cambridge-arcade, on Wednesday evening, when the competition for the best set of six cloud and marine views was decided. The prize, which is presented by Mr. Cross, was won by Mr. Dickin, who sent in a much-admired set. The prize for next June will be for the best six views of the exterior of churches and chapels in Southport and the neighbourhood, when it is hoped a large number will compete. At the Committee meeting, held previously to the above, a letter was read from Mr. Cartmel, announcing his resignation, owing to his leaving the town and neighbourhood, as Secretary and Treasurer, an office which he has most ably filled since the formation of the Club, and which was received with very great regret; and at the request of the Committee Mr. J. R. Cave, of Nevill-street, consented to undertake the duties.

Correspondence.

☞ *Correspondents should never write on both sides of the paper.*

PHOTOGRAPHY IN THE COLOURS OF NATURE.

To the EDITOR.

SIR,—Dr. Vogel's letter, on p. 318, merely contains a repetition of certain statements which he made some months ago in *Anthony's Photographic Bulletin*, to which I replied fully at the time.

Eminent scientists, Professor Sylvanus P. Thompson among others, do not admit that one colour may have several complementary colours, and my position is fully sustained on that point.

My claims to originality in orthochromatic photography were fully sustained by the Franklin Institute of Philadelphia, after giving Dr. Vogel a full hearing, and submitting my statements to him to disprove if he could, and were recognised by the award of the John Scott Legacy medal by the city of Philadelphia.

My method of colour photography is positively inconsistent with Dr. Vogel's alleged principle.

Dr. Vogel never recognised the Young-Helmholtz theory of colour vision in connexion with the subject of colour reproduction by photography until after I published my principle representing the application of that theory, and he never gave instructions for operating any process consistently with the facts which support that theory.

According to Mr. Bothamley's translation, Dr. Vogel gave *five* as the minimum number of negatives and prints that could be made to carry out his alleged principle as published in 1885. Nothing was heard about his trying to do it with three until after I proved, by theoretical considerations that three only are required in accordance with true colour theory.

Does Dr. Vogel realise that I have actually reproduced nature with what is practically a single photograph, and a device no larger than a hand stereoscope?—I am, yours, &c.,

FREDERICK E. IVES.

7, *Devonshire road, South Lambeth, May* 13, 1892.

DEPTH OF FOCUS.

To the EDITOR.

SIR,—The letter of Mr. F. H. Wenham, in your last issue, is calculated to revive the notion amongst photographers that "depth of focus" is a quality possessed by some lenses notably more than by others of the same aperture and focal length and of equal defining power in other respects. Will Mr. Wenham be good enough to show by diagram and explanation how, in such a case, the obtaining of depth of focus is possible; illustrating his argument not by reference to a pinhole stop, but by examples of two lenses of the same ordinary practical aperture and length of focus?

The rules for finding any specified amount of so called depth of focus are based in the text-books on the aperture and length of focus merely, and if any other factor steps in, these rules must be modified.

To clear the way, it may be as well to specify two or three cases suggesting exceptions which are rather apparent than real.

1. A lens having great spherical aberration may be moved to a greater distance from the focus than may a corrected lens, and still give some sort of image of a brilliant point, such as a star against a black ground, intense contrast allowing the few rays focussed at the out-of-general-focus plane to assert themselves. With such ordinary objects, however, as the photographer has to deal, these attenuated and feeble rays are eclipsed by the light from the neighbouring points, so that no real increase of depth of focus results.

2. With lenses having the most perfect spherical and chromatic corrections, the definition will be finer at the focus than with imperfectly corrected lenses, and consequently at planes so near the focus as not to be manifestly wanting. This quality should rather be recognised as finer absolute definition than as depth of focus. It comes to this, that, starting from a finer point, it is farther before a certain degree of bluntness comes in.

It may be noted that the two cases cited are opposite in character, but I have known each put in support of a claim for depth of focus, and in each case professed to be supported by photographs to illustrate the claim. When, however, the photographs were examined, it was found that the photograph taken by the standard lens, with which the others had been compared, were not focussed on the same point as those taken by the other instruments, and consequently were quite inconclusive. What definition was gained in background was lost in foreground, or *vice versâ*.

3. When the stop is moved a considerable distance from the surface of the lens, the depth of focus may be affected, but rapidity is also changed, and the depth should then be calculated according to the rapidity or effective aperture.

I await Mr. Wenham's demonstration of the position he takes up. Up to the present I look upon a claim for depth of focus as merely an advertising one, and hold with Petzval (whom I quote from memory) that depth of focus, as claimed for photographic lenses, is an expression only calculated to darken the intellect of the worker.—I am, yours, &c.,

May 16, 1892. W. E. DEBENHAM.

THE CONVENTION.

To the EDITOR.

SIR,—Pending the issue of our programme, which will be ready by the beginning of June, I ask you now to publish for the guidance of your readers who are members of the Convention the following particulars of the excursions, dinner, group, &c.:—

On Tuesday, July 12, there will be an excursion to Melrose and Dryburgh.

On Thursday, to St. Andrews and Dunfermline.

On Friday, to Dalmeny and Cramond Bridge, and to Roslyn and Hawthornden.

The group will be taken on the Wednesday, at noon, probably in Prince's-street Gardens.

The dinner and smoking concert will be held on the Friday evening in the "Waterloo Hotel."

The headquarters of the Convention at Edinburgh during the week of the meeting will be at the "Royal Hotel" and at the "Waverley Temperance Hotel."—I am, yours, &c.,

F. P. CEMBRANO, JUN., *Hon. Secretary.*

10, *Cambridge-gardens, Richmond, Surrey, May* 14, 1892.

MR. PARK'S PAPER.

To the EDITOR.

SIR,—In answer to your contributor "Cosmos," with regard to one or two statements in my paper on *Bromide Enlarging*, I hardly think they are incomplete. He says, in reference to my paper, "He usually takes his negatives for enlarging with stop *f*-32, but he omits to tell us the focal length of his lens." I do not think that the focal length of the lens has any material value, as I have always understood that *f*-32 is practically the same for all lenses, the object of using *f*-32 stop being, in this case, to obtain good definition in all planes, as well as at the edges. At the same time I may say that the focus of my lens is six inches on a quarter-plate.

Again, with reference to the density being greater in the centre when a large stop is used, he says, "He is, I think, making a statement which is possibly open to serious objection if it is to have a general application."

I think I could not do better than quote from an article, by Henry W. Bennett, which appeared in your JOURNAL a short time ago. In your issue of March 4, 1892, he says, in speaking of the rapid rectilinear lens, "A third objection is inequality of the amount of light reaching different parts of the plate when the larger stops are used, the beams of light forming the margins of the picture being much smaller in area than those in the centre. Diagram 8 shows this. A central ray, the full diameter of the stop, can pass through the lens intact, but the width of the marginal ray is determined by the extent to which it is cut by the lens mount, or the portion that the lens itself is capable of transmitting. The full diameter of the stop is shown by the dotted lines. In negatives exposed under those circumstances, where full advantage has to be taken of the rapidity of the lens, this inequality of illumination is a serious objection, as the centre of the plate frequently develops denser than the edges, and this detracts strongly from the value of the gain in rapidity."

In conclusion, as lenses are usually supplied with stops or "diaphragms" varying from *f*-5·6 to *f*-32 or *f*-64, I think there is no difficulty in describing those from *f*-5·6 to *f*-10 as large stops, and those from *f*-24 upwards as small ones.—I am, yours, &c., FREDERICK PARK.

52, *Collingwood-street, Newcastle-on-Tyne, May* 16, 1892.

FUSED SILVER NITRATE.

To the EDITOR.

SIR,—With regard to the greater sensitiveness of emulsions made with fused silver nitrate over those made with the ordinary kind, is it not possible that the fused nitrate, containing less water than the ordinary crystallised, if used in the same proportions, would practically make an emulsion with a larger excess of silver, and thus account for the extra rapidity?—I am, yours, &c., E. DUNMORE.

27, *Glenthorne-road, W., May* 17, 1892.

AMATEURS AND PROFESSIONALS.

To the EDITOR.

SIR,—I note in your latest issue an observation from "Cosmos" relating to the Bath Floral and Art Exhibition. I believe I am right in saying that amateurs are only restricted by not being allowed to affix a price to their exhibits: they are quite at liberty to sell, and no doubt will if a buyer presents himself. I do not think there is any unfairness about this. Does "Cosmos" expect amateurs to be placed on the same level as professionals? It is only proper that there should be a distinction between the two.—I am, yours, &c., W. COOPER EDMONDS.

Bath, May 15, 1892.

RECRYSTALLISED SILVER NITRATE.

To the EDITOR.

SIR,—It is not because "Cosmos" assisted his employers in cheating the public that other and respectable dealers and makers of photographic chemicals are to be considered as having always defrauded buyers by selling commercial silver nitrate at the much higher price of the recrystallised salt. I think it must be well known to you that a bath made with recrystallised silver nitrate would keep in good working condition much better than one made with commercial silver nitrate. I have some very strong evidence to this effect.—I am, yours, &c., SILVER BATH.

May 17, 1892.

A QUESTION OF "STYLE."

To the EDITOR.

SIR,—Your high-born, critical correspondent, Mr. Brown—from that serene atmosphere of literary supremacy in which he permanently resides—condescends to point out the shortcomings of some of those unworthy scribes who supply pabulum to the photographic papers. Some of those ignoramuses have actually spoken of Sirius as if Sirius were only a beam of light, instead of being a substantial astronomic actuality. Others of them have wandered wildly among sugar-bags and soap! There can be no doubt that these note-takers and note-makers should be more discreet in their lucubrations. For a fair share of this high-toned animadversion, "a Mr. Mathews" comes in. Mr. Mathews has had the audacity to employ the word "transference" when he should have said "transposition," and "unison" when he should have said "correspondence." And because he has done this his style is "pedantic and grandiose." That the uninitiated reader might the better understand, Mr. Brown proceeds to explain that certain portraits had been "out in two." In this tell-tale expression, he has himself incontinently dropped down among the feeble ones. With sufficient clearness he reveals that Mr. Brown is of that class of caterers for a sympathetic but ungrammatical public to whom we are on occasion indebted for the news, that yesterday John Smith "fell *in* the river" and was drowned. Our "penny-a-liners" do not really mean to say that John was already in the river when he fell, but only that, when he fell, it was *into* the river he fell. Furthermore, our modern Admirable Crichton dilates lucidly on "style." Now, of styles of writing there are, undoubtedly, many. There is the style of writing of Macaulay, and there is the style of writing of Carlyle. But, I pray you, in whose style of writing does the learned Mr. Brown pick up the phrase, which he launches with so much force at Mr. Mathews, that "this style of *writer* probably thinks more of sound than sense?"

Touching the topic dealt with in the phrases quoted, nothing need here be said; that is a matter which will stand or fall upon its own merits, despite the feeble flings of Mr. Brown. But, assuredly, one thing in this case is clear, our arquebusier has been hoist with his own petard. Hence Mr. Brown may at least learn this well-worn lesson, that those who reside in houses constructed with vitreous material should themselves refrain from projecting missiles.—I am, yours, &c., WM. MATHEWS.

Clifton, Bristol, May 7, 1892.

BOILS THROUGH USING OXALATE SOLUTION.

To the EDITOR.

SIR,—I would like to know the cause and cure of boils arising from the using of oxalate solution in developing bromide paper. I have been making enlargements on bromide paper all the winter, and have been troubled with small boils, till at last one has broken out on me as large as a halfpenny, which I have not been able to heal. I did not think up to now that it was the developer, but I feel sure it must be, for I have not been troubled with anything of the kind before. I have read, I think, in the JOURNAL, some time ago, of others that have been afflicted with the same complaint, and I have no doubt that both amateurs and professionals alike are troubled with the same complaint. Any information as to cure and prevention of this complaint will be thankfully received.—I am, yours, &c., S. SIDEY.

35, *Richmond-road, Dalston, E., May* 6, 1892.

FADING OF PHOTOGRAPHS AFTER DEATH.

To the EDITOR.

SIR,—In a railway train the other day a fellow-passenger said to me, quite seriously, "It is curious that when people die their photographs begin to fade." Now, as I never before heard of such a thing, I wonder if it is a kind of popular belief, for, however absurd it seems at first sight, it would be easy to bring forward any amount of proof of its correctness. Any one might, on the death of a friend, look up his photograph and find that since it was last seen a most perceptible fading had taken place, and half-naturally ascribe it to some sort of sympathy with the death of the individual, rather than to chemical changes.—I am, yours, &c.,

May 11, 1892. GEO. H. SLIGHT.

SPEED OF PLATES.

To the EDITOR.

SIR,—Messrs. Hurter & Driffield, by their careful and laborious investigations, have undoubtedly done great service to the science of photography; but, as efforts are being made to induce plate-makers to adopt their method as a standard means of marking the sensitiveness of plates, I feel bound to point out that there are serious objections to this course. My main objection is that Messrs. Hurter & Driffield's method only expresses the relative sensitiveness of plates to white light, and plate-makers, by dearly bought experience (for I put down the comparative failure of the Warnerke sensitometer to the same cause), have already found that such a scale, however accurate it may be, is very often at fault in expressing the *camera sensitiveness* of plates.

This is explained by the fact that, in most groups of objects which are photographed, the object which has to be exposed for, and which governs the length of exposure, is a *coloured* one, as, for instance, in a landscape, the grey green of foliage; or, in buildings, the grey orange of red brick. If the ratio of sensitiveness between white light and (for the sake of illustration) grey orange were the same in every plate, the proposed standard would be a suitable one; but plates vary greatly in their relative sensitiveness to different parts of the spectrum, and the adoption of a scale of white light sensitiveness would lead to errors of, in many cases, 100 per cent., if used as a guide to camera exposures.

I fully acknowledge the great need of a standard scale of sensitiveness, but it still remains to be devised. I also acknowledge that a good scale of white light sensitiveness would be some improvement on the present want of method.

If a scale of white light sensitiveness is considered "near enough," I feel sure that the use of Spurge's sensitometer, by means of light reflected by a white screen from a standard light at a standard distance, possesses practical advantages over Messrs. Hurter & Driffield's complex method. The apertures illuminating the various chambers might be numbered according to the U. S. values of the Photographic Society, and

f a low opacity were fixed upon as a standard, and the plate developed in ferrous oxalate for twenty minutes, errors due to development would be reduced to a minimum.

It will be observed that no *measurement* of opacity would be required, only *comparison* (in a suitable instrument), with a glass of the standard opacity, a fog slip of unexposed plate, developed with the other, being placed over the standard to make the requisite allowance for fog and opacity of the gelatine film. As a minor objection to Messrs. Hurter & Driffield's method, it should be noted that the standard sperm candle they use is by no means accepted by other experts as being reliable. Mr. Spurge objects to it (see last Camera Club Conference), as being subject to variation.—I am, yours, &c., ALFRED WATKINS.

Hereford, May 8, 1892.

THE PRICE OF PLATES.

To the EDITOR.

SIR,—You might allow me a small space for a few words on the above I, as a professional—or putting in my time as same—fail to see how the price of large-sized plates should be dearer in proportion to smaller-sized plates. Take, for instance, a 10×8. They cost 7*s.* 3*d.* per dozen. Now, you cannot get six quarters out of that size, and if the makers are able to sell one single dozen at 1*s.* per dozen, surely they are able to sell less than six dozen at 6*s.* per dozen, although there are nearly six plates in one. Again, to my knowledge, there is more time lost in cutting up quarters than there is in 10×8's. There are six boxes and six packings required for quarters; for 10×8 there is one box and one packing required! Now, how many amateurs use 10×8? Very few in proportion to those that use halves and quarters. Then I consider that the professional who works large plates pays more for his than the amateur, because the most of them are wrought by professionals. But, as I am only a young cock just beginning to crow, perhaps some of the old veterans will be able to give me an explanation how it is that the large plates come to be dearer in proportion to the smaller ones.—I am, yours, &c., W. T. TAYLOR.

Kirkcaldy, May 9, 1892.

[The explanation of the fact that large-size plates cost much more in proportion to smaller ones is, probably, that the price of the glass per foot advances with the large sizes. Cost of labour and risks of failure are also very likely increased.—ED.]

STAINS ON PRINTING-OUT PAPER.

To the EDITOR.

SIR,—I bought some of the above paper a short time ago, and was very pleased with it. The second lot I had was not good, as blood-red marks came in sight while I was printing, which did not go in the toning. I wrote to the makers and told them of the red marks and the poor tone; they supposed I had had hypo or other chemical on the paper, and advised the use of more gold. I bought two more sheets, cut it up, and printed at once. It came out just as bad, although I used twice the usual quantity of gold, viz., two grs. gold, to eighty grs. borax. I sent the makers some of the paper I had used, and also some new pieces which I signed, asking them to try them, and at the same time to send me two sheets direct. The two sheets have arrived, but nothing has been said about the paper I sent. Can any of your readers tell me the cause of red marks? Is it bad paper, or is it my fault? If my fault, what have I done to cause the stain?—I am, yours, &c., ALFRED MEION.

Ash Hall, Stoke-upon-Trent, May 16, 1892.

CORRECT EXPOSURES.

To the EDITOR.

SIR,—The estimation of the correct exposure necessary to be given in photographing any object is admitted on all hands to be of great importance in order to obtain a good photograph of that object. If, then, the following remarks should bring into prominence one of the essential points to be taken into account for that purpose, it will form an excuse for asking you to find a place for them in your paper.

In estimating the duration of exposure, one of the factors to be taken into account is the amount of subject included on the plate. It is difficult to express the principle more lucidly; but perhaps an example will explain what is meant, and, at the same time, establish the truth of the statement.

Suppose, then, that a portion of a uniform subject is being photographed, and requires an exposure of four seconds to obtain the best results. If, now, all the other conditions remaining the same, we substitute for the lens first used one working at the same intensity (*i.e.*, the same ratio of aperture to focus), and such that it enables the plate to represent four times as much of the subject, four times as much light will be transmitted from the subject to the plate, and therefore the exposure required to obtain a similar result to that previously obtained need only be one-fourth as long, viz., one second.

Of course, in actual practice, a case so simple in its conditions as that just given can only very rarely occur; but, nevertheless, the principle holds good, and ought to be taken into account in estimating the exposure necessary under ordinary conditions. A less abstract example will show the importance of this to the practical photographer. Often two views of an interior are required, the one to take in as much of the subject as possible, the other being of some special part of interest, and it is found that both can be best photographed with the camera in one and the same spot; if the lighting be fairly equally distributed and the different lenses worked at the same intensity, the view embracing the wider angle will require the less exposure.

It is strange that this factor should be so imperfectly allowed for in most of the exposure tables, and should be completely ignored in the instructions issued with some of the instruments sold for the purpose of determining the time of exposure. No doubt practical photographers have unconsciously learnt by experience to take this into account, and the absence of directions in the exposure tables and instruments indicating the difference to be made in cases which experience tells them require different exposures may account for the suspicion, and often contempt, with which they regard these tables and instruments.—I am, yours, &c.,

May 15, 1892. M. J. MICHAEL.

Exchange Column.

*** No charge is made for inserting Exchanges of Apparatus in this column; but none will be inserted unless the article wanted is definitely stated. Those who specify their requirements as "anything useful" will therefore understand the reason of their non-appearance.*

Will exchange Marion's 12×10 rapid rectilinear lens for good safety bicycle.—Address, T. S. SIMSON, Leven's-park, Milnthorpe.

No. 9 Ross' portable symmetrical (29,001), want Optimus euryscope, 9×7, with shutter.—Address, W. HUTCHINGS, Hairdresser, Ealing Dean, W.

Will exchange seascape, interior and exterior, flatted oil on rollers, for other backgrounds.—Address, J. JACKSON, 7, Trafalgar-street, Coventry.

Will exchange 12×9 mahogany box printing frame with plate glass for two ordinary 8½×6½ printing frames.—Address, R. SMALLEY, 12, Park-road, Blackburn.

Half-plate lens by Ross, and square camera by Spencer, 7½×7½, in exchange for a diamond frame safety bicycle, ball bearings.—Address, JAMES DENTON, 70, Sheffield-road, Barnsley.

Will exchange profile pedestal and balustrade, and iron head and body-rest, for studio accessories or exterior background, 8×7, lighted from right.—Address, GEORGE MOORE, Buckfastleigh, Devon.

Background frame (new), takes five grounds on rollers, also two backgrounds (flatted oil), in exchange for studio furniture or accessories.—Address, G. S. COUSINS, Photographer, Westgate-on-Sea.

Will exchange C.-de-V. portrait lens, by Colfier, Paris, for wide-angle landscape lens by good maker or wide-angle rectilinear.—Address, HUGH MCMASTER, Blantrey, Port William, Wigtownshire, N.B.

Six volumes of THE BRITISH JOURNAL OF PHOTOGRAPHY and *Photographic News*, 1871 and upwards, exchange for folding tripod, instantaneous shutter, or offers.—Address, H. COUCH, 11, Waterloo-crescent, Dover.

Will exchange 10×8 rapid rectilinear, in good condition, for quarter-plate camera, tripod, three double backs, and fitted with Optimus 5×4 euryscope lens.—Address, SMITH & Co., High-street, Seadon, near Leeds, Yorkshire.

Wanted, studio furniture and accessories, in exchange for background frame (new) takes five grounds on rollers; also a plain background, dark one side, light the other; also a scenic background.—Address, G. S. COUSINS, Photographer, Westgate-on-Sea.

Exchange half brass-bound camera, three double slides, Ross's R. S. and P. S. lenses, Watson's shutter in velvet-lined leather case, complete, for light 12×10 camera (must be modern), developing tent, backgrounds, or eight-inch hot rolling machine.—Address, J. ASTON BARNES, Whitby.

Will exchange landscape background 8½×7½ for cloud or graduate same size, also Optimus cabinet burnisher for cabinet rolling press, with two rollers; also quarter-plate portrait lens for Lancaster half-plate Combination Rectograph with Iris diaphragms.—Address, T. H. PITCHFORTH, Photographer, Saltburn.

A CORRESPONDENT writes: "It may be possibly of some interest to your readers, amateurs and others, to know that if they travel over Righi they will find a commodious dark room at Righi-Schaldegg, offered at very liberal conditions to any one who may use it."

THE pictures lately on view at the Exhibition of English Photographic Art in Brussels will be shown by the Lincoln Camera Club, in the galleries of the Lincoln School of Science and Art, from June 8 next. The following have promised their Brussels exhibits for Lincoln:—Messrs. H. H. Hay Cameron, W. J. Byrne, William Crooke, George Davison, Adam Diston, J. Gale, A. Horsley Hinton, Richard Keene, H. P. Robinson, Ralph W. Robieson, Lyddell Sawyer, Frank M. Sutcliffe, Robert Slingsby, Robert Terras, Henry Van der Weyde, G. West & Son, W. W. Winter. Photographers are invited to contribute exhibits, which should be sent, carriage paid, to the Secretary of the Exhibition, at the School of Science and Art, Lincoln.

Answers to Correspondents.

All matters for the text portion of this JOURNAL, *including queries for "Answers" and "Exchanges," must be addressed to* "THE EDITOR," *2, York-street, Covent Garden, London. Inattention to this ensures delay. No notice taken of communications unless name and address of writer are given.*

*** Communications relating to Advertisements and general business affairs must be addressed to* "HENRY GREENWOOD & Co.," *2, York-street, Covent Garden, London.*

NOVICE (Leeds).—The "stain" is due to light getting into the dark slide through the top of the shutter groove.

A. P.—To our knowledge there is nothing on the market resembling the screen of which you send us a photograph. It would possibly be a commercial success.

W. HARVEY.—If the sulphite of soda was in the form of a white powder, it no doubt accounts for your trouble. A village chemist's shop is not where we should expect to get good sulphite of soda.

S. BOWYER.—It is only by working with the best materials that you can expect to obtain the best results. You had better procure those specially prepared for the purpose, notwithstanding that they are somewhat more costly, particularly in the experimental stage.

EXPERIMENTALIST asks if bitumen more sensitive to light than that usually sold, namely, that which has been treated with ether, &c., is to be had commercially.—We believe it is. We fancy it is supplied by several London dealers.

E. T. CUMMINGS.—The stains on the negatives arise from imperfect fixation. It is not sufficient to leave the plates in the hypo till all the bromide of silver has disappeared. They should be allowed to remain as long after the bromide is dissolved as the time it took to dissolve; a little longer does no harm.

LINCOLN.—Probably the fault lies with the negatives. To obtain good reproductions of engravings, the negatives must be strong, with the lines as nearly bare glass as possible. The best results with this class of work are got with wet-collodion negatives. With dry plates, only those specially prepared for photo-mechanical work should be used in copying engravings.

ALOE.—Clearly the shutter does not work quick enough. Considerable movement of the figures is apparent, while the plate is much over-exposed. You say the shutter was set for its quickest, and, as we know that it is one of the most rapid in the market, we cannot but surmise that there is something that retards its movement, such as dust, or maybe some portion is slightly bent.

BROMIDE says: "I have a ten-inch focus portrait lens, with both back and front combinations measuring three inches, no name on mount, but the stops and under side of the lens mount are marked with the letters 'L. C.' Can you tell me from this who is the maker of the lens and the value of same?"—The maker of the lens was Coiffier, of Paris. It is probably an excellent instrument.

S. K. G. says: "Kindly let me know if 'immersing bromide prints in an alum bath to harden' is calculated to render them more liable to fade; and, if so, would subsequent washing in clear water prevent it?"—We do not apprehend that the proper use of an alum bath with bromide prints is likely to conduce to fading, hence subsequent washing is of little consequence in that connexion.

M. FRANKE.—There need be little difficulty in photographing the collection of old china if you are careful in illuminating the subjects. Reflection and false light must be avoided. A single lens, or one of the rapid type, will answer very well. The formula quoted is an excellent one for treating the plates by. A pale yellow screen should be used with them. Give a full exposure, but do not over-expose.

FITZ B.—1. For copying oil paintings, orthochromatic plates are necessary. 2. There are several manufacturers of gelatino-chloride paper whose advertisements will be found in our outer pages. 3. We cannot tell you where to find the description "of a self-made good lantern for the dark room." Surely, out of the numerous advertisements of dark-room lamps, you should be able to select one suited to your requirements.

RICHARD PAINTER (Blandford) asks if double albumenised paper and thickly albumenised paper are not one and the same thing.—No. A paper may be thickly coated without being doubly coated, and *vice versâ*. The double method strictly consists in applying albumen, whether salted or unsalted, to the surface, and then coagulating this by steam or analogous means, the salted albumen being then applied. It is evident that this latter cannot sink into the paper, but must remain on the surface, thereby conferring brilliance.

NOVICE IN CARBON complains that he cannot succeed in getting his carbon prints to adhere to the temporary support for development, and asks the reason.—There may be more than one reason for the trouble. 1. It may be that the "safe edge," that is protecting the margins of the negative from the action of light by means of strips of opaque paper or black varnish. 2. The tissue may have become insoluble, in which case it will be impossible to make it adhere. 3. Possibly the tissue was allowed to remain for too long a time in the water before it was squeegeed on to the support. These are the principal causes of this trouble.

J. WESTWOOD asks if any English firm supplies paper *ready prepared* for printing by the Woodburytype and Stannotype processes. He says "he believes it is the usual Rives paper, which has undergone a special treatment with shellac and heavy rolling, and is told it is not to be had in this country."—The paper, ready for use, is an article of commerce in some parts of the Continent. Liesegang, of Düsseldorf, if we mistake not, supplies it. Possibly, however, some firms who work Woodburytype here will supply the paper.

R. A. J. writes: "Can you tell me if the large negatives, reproductions of the paintings in some of the Continental galleries, from which the excellent prints to be seen in the shops abroad and sometimes here, printed in carbon, are by the wet-collodion process or on dry plates? I presume, whichever process is employed, the plates are orthochromatised."—The majority of the negatives of the class referred to, if not all, are by wet collodion. The reproductions of our National Gallery pictures by Braun a few years ago were by the wet-collodion process. In all cases the plates are orthochromatised to obtain the fine effects we see.

P. BOWMAN.—Supposing the varnish be the ordinary spirit varnish, which is usually employed for negatives, there need be no difficulty in removing it so that the negative may be intensified. Place the plate in a dish of strong methylated spirit, and let it soak for a quarter of an hour or twenty minutes, with occasional rubbing with a tuft of cotton wool. Then empty away the spirit and apply fresh, and repeat the operation. Then rinse the negative with a little fresh spirit. If by this time the whole of the varnish is not removed, more spirit must be used. In very obstinate cases a small quantity of caustic potash may be dissolved in the spirit to increase its solvent power.

F. E. G. says: "I want the loan of some good negatives from which to make enlargements. The subjects must be interesting to the general public—views, figures, cherubs, sculpture, &c., photographs of good steel engravings or pictures that are not copyright. I would be much obliged if you, or any of your readers, could advise me how best to obtain such negatives on reasonable terms. I enclose for your inspection a photograph on which the name and address has been photographed. I have no intention of registering this novelty, but would be glad to have your opinion as to whether this style could be made copyright."—1. We can only advise you to advertise for such negatives as you require. 2. Copyright is only applicable to the pictures themselves, not to the style in which they are done.

H. WILLIAMSON sends us some photographs of prize medals gained by a business firm, who intend to use them for advertising purposes. He says: "The people have returned them, saying that they are of no use, as they are not good enough. I enclose a print of some coins they have sent me. They say, unless my work is as good as these, they will cancel the contract. Now, I must confess that my work, as you will see, is not nearly so good as that forwarded by them. Can you kindly suggest any means by which I can obtain a better result? I shall esteem it a favour if you will please return the prints in the stamped and addressed wrapper."—The specimen print is certainly very much better than the other, and there is a very good reason why it should be. The negatives were not made direct from the coins, but from reproductions of them in plaster of Paris, hence their superiority. Our correspondent should get his customers to have their medals so reproduced in the same way, then he will be able to get a similar result. Usually the plaster of Paris is slightly tinted with some dark pigment, such as burnt umber, to take off the excessive whiteness, which is an assistance in the work.

PERPLEXED says: "Will you please give me your opinion of the stains on the enclosed prints. We have been troubled with them now for some weeks. They do not appear on all the prints in the same batch. For the first few weeks they only came on the cabinets, now we have them on different sizes. I may say the mounts we are using are the last of a large stock, and we have never been troubled with marks or stains until now. Before mounting, the prints are clean and good. If they are kept unmounted for weeks, they are still the same. The prints are thoroughly washed, and every care is taken as regards cleanliness in every process. We always mount with starch. Now, we have tried different makes, Glenfield Photographer's Starch included, but the stains are just the same. Now we are at a loss what to do, and should be glad if you could help us out of the difficulty."—It does not appear that the mounts are at fault, although they may be. Any impurity in them could only be detected by chemical analysis. The stains are similar to those produced by imperfect fixation and washing. Mount the half of a print on one of the mounts, and compare it with the half print that has not been mounted at the end of a few days, and let us know the result.

PHOTOGRAPHIC SOCIETY OF GREAT BRITAIN.—At the Technical Meeting, May 24, the properties of the new concentric lens of Messrs. Ross & Co. will be demonstrated. Members are invited to bring their best lenses for comparison with it.

LONDON AND PROVINCIAL PHOTOGRAPHIC ASSOCIATION.—May 26, *The Photographic Study of Clouds and Lightning*, illustrated by slides, Mr. A. W. Clayden. June 2, *The Tele-Photographic Lens*, Mr. T. R. Dallmeyer. 21, Outing to Eltham.

PHOTOGRAPHIC CLUB.—May 25, *Developers for Bromide Prints.* June 1, *Photo-micrography*, Mr. T. Charters White. Outing next Saturday (21st inst.) to Eltham, under the guidance of Mr. E. A. Newell. Train from Cannon-street at fifteen minutes past two.

CONTENTS.

THE BRITISH
JOURNAL OF PHOTOGRAPHY.

No. 1673. Vol. XXXIX.—MAY 27, 1892.

LENS DIAPHRAGMS FOR BINOCULAR CAMERAS.

As to the utility and convenience of the Iris diaphragm there will not be two opinions. But this useful appendage to the lens may prove quite different when applied to a single and to a double-lens camera. The lovely smoothness with which the leaves fold and unfold in response to the touch of the button or the rotating ring outside is such as to charm every one who has once experienced its use. And yet this very facility of movement and adjustment may, and often does, prove hostile to its effective employment in the case of stereoscopic cameras.

It is exceedingly difficult to adjust, by means of the engraved graduated index-ring outside, a pair of lenses so that each shall be identical with its fellow; and, unless they are absolutely identical, there will be a lack of equality between the two pictures, one receiving a relatively longer exposure than the other. In some cases even the engraved lines of the index circle are, assuming their accuracy of position, of such a breadth that the mere adjusting the arrow-head to the one margin or the other of the line will cause a difference.

For this reason we have always recommended, and employ, Waterhouse diaphragms in the lenses of our stereoscopic camera. And even these diaphragms are not altogether an unmixed blessing, especially as supplied by our best opticians at the present day. They give us too much for our money. A multiplicity of stops, each differing from another in but a slight degree, is apt to bewilder; and our advice to a tourist using a binocular camera is to select only three, or at most four, and leave all the others at home. Nay, more, he will greatly consult his convenience by "pairing" his stops so as to render it impossible for dissimilar ones to be employed even when working under the greatest conceivable pressure of time.

Let us explain. At a cursory glance there is no appreciable difference between, say, *f*·27 and *f*·32, that is, when the stops are merely looked at, and their dimensions estimated without examining the figures, and such an unequally matched pair may be, and to our certain knowledge have been, worked simultaneously, with the result that one picture is more fully exposed and denser than the other, and wise men, at the societies or clubs where they are exhibited, account for the difference by the supposition that one lens must have become discoloured without its being apparent, and therefore slower in action. The system of pairing stops which we recommend is simple in the extreme. It consists in removing the black, by means of emery paper, from the thumb piece of each alternate pair of stops. Thus, selecting from the battery of diaphragms, say, *f*·32, *f*·22, *f*·16, and *f*·11, the thumb pieces of the first and third of these will be black, while those of the second and fourth will be bright brass, rendering a mistake as between adjacent sizes quite impossible, as a bright stop in one lens, and a black one in the other, would indicate inequality. It need scarcely be said that this brightening must only apply to the projecting thumb piece, and not to the area of the diaphragm.

We have spoken of the difficulty that may arise in the case of having a pair of lenses with Iris diaphragms accurately matched. But this may be effected by the application of the check system now so frequently adopted with iris diaphragms, by which at certain apertures there is a check to further rotation by the action of a spring point falling into a notch. If this were made sufficiently stiff, and identity between the two lenses could be relied on, this would serve the purpose; but only equalling the efficiency of Waterhouse stops to which the pairing system we have just described has not been applied, for there would still be the possibility of one size being employed in one lens, and another in the other. The real remedy, could it be easily effected, would consist in having the pair so connected one with the other that both would be automatically operated by one movement. So much mechanical ingenuity exists among opticians and photographers that we do not doubt of this desideratum being accomplished.

THE PRESERVATION OF MODERN PRINTS.

The question of the permanency, comparative or otherwise, of modern prints by various processes is one that is constantly recurring; but, in most of the discussions that have taken place, the major portion of the attention has been devoted to the stability of the image itself rather than to that of the support. In other words, the point that has been the more carefully considered is whether the metallic or other deposit forming the image is subject to change with lapse of time or under stress of atmospheric conditions, while the inalterability of the paper support has been comparatively ignored. It is true the question of the possible discolouration of the paper from one cause or another has been discussed on more than one occasion; but this class of deterioration is more particularly connected with the photographic side of the question, since it generally arises from faulty manipulation, and may therefore be placed under the heading of fading or alteration of the image, but the physical deterioration of the support itself has scarcely yet been adequately considered.

In confining ourselves to modern prints, we do so because the fading of albumen prints has come to be almost universally, and perhaps correctly, set down to the liability of the albumen itself, not only to decompose, but also to form silver compounds that are peculiarly liable to decomposition, both spontaneously and under slight atmospheric provocation. Silver images in collodion films have long been regarded as far more permanent than the ordinary albumen prints; indeed, it has been claimed for the developed collodion negative image that it is absolutely permanent within the limitation we have already referred to.

Similarly it has been alleged in favour of gelatino-bromide and chloride pictures that they are, if not absolutely permanent, at least practically so, partly in the case of developed prints, by reason of the different composition of the image, but mainly because gelatine is supposed to be free from the peculiar tendency of albumen to decomposition, and to the formation of decomposable products. This may or may not be the case, but there is probably a good deal of truth in the claim; still, it may be asked, is gelatine itself wholly free from reproach in a physical sense, or, for that matter, even chemically?

Personally, we are very far from taking that view; on the contrary, given two prints, one on albumen paper and the other with gelatine as the basis, equally carefully treated in preparation, and equally free from chemical impurities, we consider that the albumen print is better calculated to stand the ordinary vicissitudes of our climate than the other. This may appear to many a strong if not a reckless statement, but let us say a word in explanation of what we really mean. What *are* the "ordinary vicissitudes" of climate in this country? Well, damp is certainly the first, and changeability, both as regards temperature and degree of moisture, comes next. Beyond these, the abnormal conditions to which a print may be submitted cease to be ordinary, and if we choose to hang our photographs in an atmosphere of sewer gas, or in a chemical factory, we must expect them to suffer. Alternations of heat and cold, of dryness and moisture may therefore, we think, be safely taken as representing the conditions to which the majority of photographers are subject.

Now, which, we ask, is the more likely to pass through a lengthened exposure to such conditions without change, pure coagulated albumen or pure gelatine? We are treating the respective prints as if they were theoretically perfect, that is, consisted only of pure gelatine or albumen and metallic silver, or some perfectly insoluble and equally inert compound thereof. If it is not possible in practice to attain to this state of affairs, it is no more difficult to make a fairly near approach to it with albumen than with gelatine; perhaps, really, it is easier. Now, pure coagulated albumen is one of the least changeable of all the forms of animal organic matter, and little, if at all, subject to decomposition from moisture; while pure gelatine—well, perhaps the less said the better. Gelatine, even when hardened as completely as it can be with ordinary or chrome alum, is still very subject to swell and change under the action of moisture; but the treatment to which the majority of prints are submitted, even when they are "alumed," is scarcely such as to ensure the maximum burdening effect being attained.

A wide difference is to be recognised, however, between developed and printed-out proofs. Not only has the hardening effect of the development to be taken into consideration in the first case, but it is an almost universal practice to use alum in the preparation of the emulsion, and also in a clearing and hardening application to the print after development. On the other hand, the printing-out papers have usually perfectly soluble films, better colours being obtained under such conditions, and are also deprived of the indurating action of development, while alum may or may not be used after toning and fixing; so that, on the score of hardness alone, the developed print would seem to have a better chance than the other.

But emulsions for development are made under such conditions that the gelatine is seldom or never for long submitted to the action of free silver, while the printing-out emulsion contains as one of the essentials to its successful use an excess of soluble silver salt, and this exists in the film itself in a more or less dry state until the time comes for toning. Here, then, we can foresee a greatly enhanced opportunity for the formation of dangerous silver compounds which, though they may show us immediate signs of their presence, may still be there to work injury in the finished print if aided by warmth and moisture.

It is many years since the practice was introduced in connexion with albumen prints of impregnating them with some substance more or less impervious to water or moisture in order to render them less liable to deterioration from such influences. It is not necessary to cite instances of the value of such treatment, it may suffice to say that such simple treatment as coating with collodion, polishing with wax or encaustic paste, a preparation of wax or the more elaborate system known as enamelling, have all been proved to add to the permanency of a silver print, though not to render it altogether unalterable.

From what has been said respecting gelatine it seems more than ever necessary, or, at least, desirable, to apply some such treatment in order to render the prints as little subject to change as possible; for, while it may fall short of rendering them absolutely permanent, it is very little trouble, can do no harm, and serves to impart a feeling that we have at least done the best we can.

The methods we have enumerated in connexion with albumen prints are equally applicable to gelatino-bromide or chloride surfaces; but their preservative effect is far inferior to that of another method we shall name, and which with gelatine is infinitely more effective than even with albumen. We refer to the application of a coating of aqueous solution of shellac, made by dissolving bleached lac by boiling in a weak solution of borax. This forms a pale yellow solution, which dries without colour upon paper, and forms a perfectly insoluble film, is perfectly flexible—short, of course, of actually creasing the paper, when, of course, it will break, and, in fact, making the print as nearly waterproof as anything will. It may be made to dry without gloss, or, if preferred, a high glaze can be given to the surface, and it is equally applicable to the smoothest and roughest papers.

But the chief point of advantage in its use is, that whereas with an albumen print the coating of varnish would be entirely on the surface if the print were floated, or in the pores of the paper in addition if immersed, in the case of gelatine, floating alone suffices to thoroughly *impregnate the gelatine film* with the waterproofing material, and the treatment may be extended to the paper support or not, as preferred. The fact of the pores of the gelatine being filled with shellac ensures that the individual particles forming the image are surrounded with waterproof material, and so at any rate approximately isolated, and thus, if the seeds of change should exist within the film itself, their power for harm is greatly lessened, if not altogether destroyed.

The varnish is made by dissolving about one hundred grains of borax in a pint of water by boiling in an enamelled saucepan, and when dissolved adding an ounce of good bleached lac broken into small fragments. Continue boiling and stirring until the shellac is dissolved, then filter first through muslin, then through bibulous paper, and finally set aside for some days until a fine sediment falls, and leaves the solution clear and bright, of a pale straw colour. It may be made stronger or weaker, as desired, using the borax and lac in the proportion of about 1 : 5 respectively.

On this varnish the print may be floated, or it may be

altogether immersed, and then hung up to dry. We prefer to dry the prints first, and immerse them in that state in the lac solution until quite limp, then pin up to drain and dry.

USE AND ABUSE OF THE HAND CAMERA.

Close observation convinces us that the hand camera in some form or another is destined to keep its present popularity for a considerable time, inasmuch as the uses to which it is specially applied are not likely to disappear before the means of ministering to them. As an item of the tourist's or traveller's outfit, as the companion of the artist, the newspaper correspondent, the architect, and the antiquary, and many others, the hand camera has, as it were, opened up for itself a field of indispensability which the stand camera would never, *per se*, have been capable of creating or occupying; and it is on these grounds that we are induced to predict a long lease of life for it rather than on its partial supersession of the ordinary camera among those who fail therewith to secure the *desiderata* of lightness, compactness, and portability in combination with efficiency as an instrument of precision for different kinds of photography.

Among those photographers, however, to whom the employment of the hand camera is not dictated by a necessity equally as great as that which obliges the classes of persons previously mentioned to confine their photographic work to the fruits of that instrument, we are not confident that the latter is sure of a continued popularity. It is seldom that we find, amid the enormous number of photographs taken by means of the hand camera, that the quality of the work, either in an artistic or technical sense, approximates to that which is executed in the usual way, although we hasten to allow that there are a large number of photographs so produced which are at least creditable on those two counts. But of really good hand-camera work there is no plethora. We have invariably found that that which fairly challenges comparison with the best stand-camera pictures is the production either of men of exceptional skill, who have devoted a large amount of time and study to the proper use of the hand camera, or of those who are equally expert in picture-making in the common method.

It is consequently, because it appears to us that the production of the finest quality of results with the hand camera demands a high degree of skill in addition to that necessitated by stand photography, and which is, therefore, doubly difficult of acquirement, that we should not be surprised if, in course of time, the hand camera for ordinary work was quite relinquished by those whose aspirations it failed to assist towards realisation. At present, such cameras are largely employed under circumstances which preclude good pictures being made except by a miracle. For example, they are much used for taking difficult architectural and dark landscape subjects pure and simple, without any moving figures in the pictures, for interiors, and for groups. We leave our readers to conjecture how often, in the first case, the lines of the subject escape distortion, how near to correctness the exposure approximates in the second and third, and in the fourth how the grouping and lighting are satisfactorily accomplished without the aid of a focussing screen.

In such work as this the hand camera, particularly in the case of those of only moderate ability, takes away in technical or artistic qualities what it gives in portability and convenience. For its thoroughly successful use, it entails the expenditure of a fund of common sense, thought, care, and downright cleverness which far exceeds the average possession of these qualities. On the single score of exposure, we maintain that, for most subjects, excluding moving figures, the drawback of not being able to carefully examine the image on the screen deprives one of the power of exercising that judgment which, in the absence of artificial aids, is absolutely essential to giving approximately correct exposures with any degree of certainty. Hence it is that we so rarely find hand-camera work properly exposed. As to pictorial composition, careful selection of subject, arrangement of light and shade, and proper proportion of picture, they, if not out of the question, are rendered vastly more difficult of attainment with a hand camera than otherwise. In short, the hand-camera worker's mind is, by the necessity of his position, too often *in* his camera and its appurtenances, instead of in the picture, with disastrous results to the latter.

The sphere of the hand camera is, as we have already remarked, clearly defined. Besides those to whom it is a constant *sine quâ non*, it has a distinct claim upon the ordinary amateur worker at times, as, for example, in street scenes, in animal work when it is necessary to follow up the subject, and on many other special occasions when the use of a camera on a stand would be out of the question. In these respects the hand camera—though the quality of the pictures must too often partake of the nature of compromises—occupies legitimate ground, and we believe, considering the ingenious mechanical improvements of which it is constantly the subject, will continue to do so in the future to increased advantage. By no means do we wish these remarks to be accepted as intended to deter the users of hand cameras from this kind of work; on the contrary, we indicate such a field of photography as one to be cultivated with every assiduity. That is a proper use, and not an abuse, of the hand camera, and we applaud it.

At the commencement of the season for outdoor work we have perhaps not unfittingly invited attention to the fact that hand cameras are too often employed on subjects which lie peculiarly within the domain of the stand camera. One fact more than another confirms us in our view that ere long the hand camera will be largely abandoned by those who abuse it in the manner we have pointed at, and that is the unsatisfactory nature of the pictures it invariably yields in ordinary hands. Where it is always possible to produce better work with less trouble, there surely may we look for dissatisfaction; and, as dissatisfaction is a strong incentive to progress, the moral will doubtless not be lost on many hand-camera workers. There is a proper place for the hand camera in photography, which we have clearly traced out; but, when it is employed on stand-camera subjects pure and simple, we are not sure that photography is not harmed rather than benefited by the facilities it affords of degrading its capabilities for picture-making.

A New Fixing Agent.—We are informed that a new fixing agent in place of hypo will shortly be introduced by a firm of manufacturing chemists. The nature of the compound is, so far, unknown to us, except that it has an acid reaction, and that it will work at a higher degree of dilution than the hypo solution.

Fine Art Exhibition.—The sixth International Exhibition of the Fine Arts in the Crystal Palace, Munich, which will open to the public on the 1st of June, is, we are given to understand, one of the finest hitherto held. As the Bavarian capital has always been a home for fine art it, would be surprising if its exhibitions were not great successes. Etching and engraving find a place in the Exhibition, but

not photographs or photo-engravings. It is a little surprising that the latter do not, for the art is worked to a higher state of perfection in Germany, perhaps, than in any other part of the world. More particularly is this the case with the reproduction of paintings both by the old and modern masters. However, photogravures are not shown.

Old Presentation Prints.—*Apropos* of the recent exhibition of very ancient silver prints, it used to be the custom with most of the old photographic societies to give a presentation picture to its members annually. These pictures were generally about the best photographs that could be obtained at the time. The negatives were made by various methods and modifications, and the prints sometimes by one process and sometimes by another. Now, there must be thousands of these prints still in existence. If a collection of them, whatever be their condition, could be got together, it would be interesting, as well as instructive. In a measure it would illustrate the state of the art, at its best, at certain periods, and what was done by different processes; also, in the case of prints by the various methods, how they have stood the test of time.

To Prevent Unsightly-looking Bottles.—Most photographers have an experience of the untidy and unsightly appearance of the bottles on their shelves, caused, after pouring, by the running down of a portion of the contents over the sides of the vessel, and crystallising there, or perhaps sullying the label. According to a correspondent of the *Chemical News*, this can be entirely obviated by simply painting the lip or rim with melted paraffin. Care should be taken to cover only the side of the lip—none should be put on the upper surface. It can be accomplished most easily by using a small hog-hair brush, and a wax of low melting point, such as is used for embedding sections. It will be found that, besides preventing the solution trickling down the outside, it enables the reagent to be delivered in single drops, without resorting to the plan of partially withdrawing the stopper. Those who have vainly endeavoured to deliver drops from the mouth of a bottle will appreciate the advantage of the latter recommendation.

The Aërial Graphoscope.—At a recent meeting of the Physical Society was exhibited, as a "new instrument for showing the effects of persistence of vision," an apparatus under the above title, which, we presume, is the same instrument (or a similar one) as that exhibited at the last exhibition of the Photographic Society of Great Britain in Pall Mall. It consists, as visitors to the Exhibition will remember, of a narrow wooden lath mounted on a whirling machine so as to be rapidly rotated in its own plane. When rotated it presents the appearance of a nearly uniform screen or disc, owing to the persistence of impression. For exhibiting the latter effect the instrument is, of course, a useful, if cumbrous, affair; but for practical lantern projection it is, as we have before pointed out, practically worthless. The loss of light is, perhaps, ninety-five per cent., and there is the further disadvantage of this ninety-five per cent. going to illuminate the rest of the room, though, of course, it would be practical to place a black-velvet screen behind to absorb this; but then the *raison d'être* of the machine would be gone.

Photochemical Action.—Messrs. P. Askenasy and Victor Meyer have been experimenting upon the action of light upon mixtures of gases capable of detonation. Of particular interest to photographers are those upon the photo-chemical induction of chlorine. They say that, in regard to Draper maintaining that a chlorine-detonating gas, composed of chlorine and hydrogen, previously exposed to the action of light, possesses the power of continuing to form hydrochloric acid even in the dark, their experiments prove the observation to be incorrect. Bunsen and Crowe have rejected the observation as being incorrect, showing that chlorine which had never passed outside the laboratory through a glass room exposed to the heat of the sun, and was then mixed with hydrogen similarly treated, remained inactive on mixture with the latter in darkness. The first-named experimenters, in order to remove every possible objection and element of doubt, repeated these experiments with every precaution against possible contamination of the gases, and made the exposure to light continue for several hours, concentrating the rays of the sun (in July) by a concave mirror. No combination or production of hydrochloric acid occurred.

A Unit of Measure of Light and Colour.—At the Physical Society, Mr. Joseph W. Lovibond read a paper on this subject, and illustrated it with diagrams, models, coloured charts, &c. The principle of the measurements depends on the selective absorption of the constituents of normal white light by coloured glasses, red, yellow, and blue. The depths of tint of the glasses are carefully graduated to give absorptions in numerical proportions. For example, two equal glasses, each called 1-unit red, give the same absorption as a 2-unit red, and so on. The units of red, yellow, and blue are so chosen, that a combination of one of each absorbs white light without colouring the transmitted light. Such a combination he calls a "neutral-tint unit." By the use of successive neutral-tint units, white light can be gradually absorbed without showing traces of colour, and the number of such units required to produce a complete absorption is taken as a measure of the intensity or luminosity of the white light. The influence of time of observation on the penetrability of different colours was illustrated by diagrams, the results of 151 experiments in colour being explained. Mr. and Miss Lovibond showed the methods they used for colour-matching and measuring.

An Unrecognised Use of Photographs.—A few weeks ago it will be remembered that a lady was muleted in penalties and costs for lending season tickets of admission to the Crystal Palace to other persons, such tickets being "not transferable." Now, there is no question that season tickets for exhibitions, railways, &c., are very frequently used by people to whom they were not granted, and who have no right to utilise them. Impositions of this kind are very difficult of detection under the present system; but, if photography were made use of, this fraud might at once be exposed. Those granting season tickets, whether for exhibitions or railways, can, of course, fix their own conditions. If one of these were that the holder was to have his photograph attached to it, bearing the Company's impressed stamp, fraud would be next to impossible, and photography, from a business point of view, would be benefited. Many portraitists would be glad to make terms with the companies to take portraits for the purpose at a reduced rate, on the chance of obtaining orders for duplicates. It is rarely that a portrait is taken, if it is satisfactory, that a number of duplicates are not ordered. Here is a hint to railway companies and others. We are quite aware that the idea is not new, and, if we mistake not, has been carried out in connexion with more than one international exhibition on the Continent with success.

What is "Right Exposure?"—At the present time there are before the photographic world various "exposure tables" and different forms of instruments for gauging the quality of the light, their object being to enable the inexperienced worker to rightly time his exposures. Now, if we examine these several tables and instruments, we find there is a great diversity between them. Yet each have their advocates, who assert for them that they are perfectly reliable. Now, how is the discrepancy to be accounted for? Perhaps it may be from the great latitude of exposures allowable with modern dry plates. Any error within reasonable margin may be compensated for in the development. But this is not all. Ideas as to what is a correct exposure differ widely. Given three workers—not novices—with the same plates, if they, independently of one another, took the same view, the chances are that they would all give different exposures, and that difference might vary as much as two or three hundred per cent. Yet each would produce good printing negatives. Some operators go for a minimum of exposure and a somewhat forced development; while others proceed conversely—give a maximum exposure, and follow what some would term a restrained development. Seeing that both classes of workers get equal results, who shall decide as to what is "proper exposure?" Or is there such a thing?

Safety of Electric Lighting.—The popular belief in the perfect safety from fires of electrical modes of illumination has received several rude shocks of late, so much so as to leave a possibility of the opposite extreme of belief being held. But a lecture recently delivered by a well-known expert, Mr. W. H. Preece, at the rooms of the Royal Institute of British Architects, puts the matter in its proper light. The lecturer admitted that sometimes the light was not safe, but the danger chiefly lay in the use of imperfect materials in cheap contract work. Good design, perfect materials, first-class workmanship, and rigid inspection combined the elements of complete safety. In proof of this Mr. Preece stated that no fires had occurred in buildings fitted up under the rules and regulations, and inspected by the officers of, the insurance companies in this country. Those of our readers who contemplate the erection of an electric-light installation, or the alteration of existing fittings, will therefore do well to remember Mr. Preece's advice that everything ought as much as possible to be kept in view, and that the conductors ought not to be hidden under wainscots or floors, or above ceilings. He further stated that the glow lamps excited by three watts per candle was at present the most perfect source of domestic light, and when the patent expired—in a year or two—would be obtainable at about one-third of the present price.

Unsafe Hotel Dark Rooms.—As the photographic season has now fairly commenced, and during the next few months tourists, both at home and abroad, will frequently have to avail themselves of the accommodation provided at hotels for changing their plates, it will not be inopportune to give a word of caution as regards the light used. This is often of an unsafe character, particularly with highly sensitive plates. Here is a case in point, which has just been brought to our notice. A gentleman, recently travelling on the Continent, wanted to change his plates. He was shown into the hotel dark room. It was illuminated with a window about eighteen inches square, of very deep ruby glass, which admitted very little light indeed. After waiting for the eyes to get accustomed to the almost darkness, it was noticed that what little light there was had a peculiar tint. As our friend would as soon think of travelling without his pocket aneroid as he would his spectroscope, the latter was soon brought into use. It was then seen that, little as was the light passed, it contained a considerable amount of blue and some green—quite sufficient to fog a rapid plate, even with but a moderate exposure to it. However, by working in a corner of the apartment, shielded from the window, the plates were changed in safety. As every one does not carry a pocket spectroscope with him, tourists would do well, when using strange dark rooms, as a matter of precaution, to look upon the light with suspicion, even if it be perfectly safe, and expose the plates to it as little as possible.

Bleached Lac.—The basis of almost all the photographic varnishes, as most are aware, is shellac. Usually the bleached resin is the kind employed. Now, all who have made the varnish know quite well when the ordinary white lac is employed that only a portion of the resin is dissolved, and that a considerable residue remains, which takes a long time in subsiding, and is very difficult to filter out if filtration be resorted to. Another point in connexion with bleached lac of the usual kind is that if it be kept long after it is bleached it becomes brittle and more or less insoluble. This deterioration may, however, to an extent, be retarded by keeping the resin damp. Reference to this subject is brought about by the fact that we were recently shown a sample of white lac that was free from these defects, except that of becoming brittle, but even that did not appear to interfere with its other qualities. In appearance it was silky white. It had been exposed, dry, to the atmosphere for some weeks, and was so brittle that it could be easily broken with the fingers. When an ounce or so was placed in common methylated spirits, it dissolved readily, and made a perfectly clear and nearly colourless solution that proved an excellent varnish. Unfortunately we could learn no particulars about it, except that it was of foreign production, probably German, and was about three times the price of that sold in England. The method we believe usually employed in bleaching lac in this country is to dissolve the resin in a boiling alkali, then add hypochloride of lime, and afterwards pour in some mineral acid. Chlorine is liberated, which bleaches the lac, which at the same time separates largely mixed with lime, which is not altogether separated in the after-treatment. Some years ago the following method was published:—The lac was first dissolved in boiling alkali, then chlorine gas was passed through the solution, when the lac was precipated free from colour. We tried the process at the time, and obtained a perfectly colourless lac, which behaved in precisely the same way as the sample just referred to. Possibly it was bleached by a similar process.

PHOTOGRAPHY IN MILITARY RECONNAISANCE.

The importance of knowing the topographical features of a country where military operations are likely to take place is so far recognised by the authorities that officers have to pass examinations in road-sketching, map-making, and reporting of features of ground prior to receiving appointment on the staff.

Much has been done in the way of simplifying instruments, with a view to obtaining particulars quickly, and making sketches rapidly, but it is freely acknowledged that very few men can draw well, and when they have artistic ability the disposition is to make pretty sketches and maps rather than give *exact* reproductions of what they see. Naturally photography has been considered as a substitute for eye-sketching, and, although only taken up in isolated cases, it has been shown that it is of the greatest assistance in reconnaisance.

Lieutenant F. E. Davies, of the Grenadier Guards, recently read a paper at the Royal United Service Institution on *The Employment of Photography in Reconnaisance*, and also showed examples of maps made of the country passed through during a journey extending over some weeks, in very bad weather, and illustrated the map with marginal photographs instead of the orthodox sketches.

The value of these pictures in connexion with maps was favourably commented on by general officers and professors present at the lecture, for it was at once recognised that if definite particulars were wanted respecting a bridge to be blown up, or a fort to be captured, the style and proportions could be at once gathered from a photograph with but little additional information.

Then, again, with respect to time, a sketch must of necessity take considerable time, even in the experienced draughtsman's hands, and, for the same reason that special correspondents of our leading illustrated papers have recourse to photography to get their details and general disposition of the groups or crowds forming the special subject of interest, so military officers, whose duty it is to report what is going on in the enemy's country in time of war, or for manœuvring purposes in time of peace, will find it of invaluable assistance.

The choice of apparatus is an important matter; but, as Lieut. Davies justly said, as there are no less than eighty different kinds of hand and portable cameras in the market to choose from, there should be little or no difficulty in finding one suitable for the particular purpose required. It must, of course, be portable, and capable of being rapidly and sometimes secretly used. The films or plates must be so arranged that they can be transported great distances without fear of breakage, or suffering from meddlesome tampering prior to exposure, or on being returned for development. As the map is constructed the photograph representing the part desired to be illustrated would bear a number, and when printed would be placed on the position assigned to it by a similar number on the margin of the map. In this way the officer, if need be, could send an orderly back with the map and negatives to be developed at headquarters for the information of the general.

If necessary, development and printing could be done in the field, and by using bromide paper it was shown in about a quarter of an hour after a negative was sent out of the lecture-hall, it had been developed and a print made. A number of negatives could be developed and printed proportionately quicker, and, in fact, it was stated by one of the speakers that five or six had been so treated in half to three quarters of an hour.

For military purposes those troubles so familiar to photographers, such as yellow stains, hardness, &c., may be disregarded, as accurate indications are more important than pretty pictures. The large number of photographs shown indicated very fairly the average excellence of the result, and, when it was stated that some were taken on a cloudy day in February with no sunshine, and snap-shot exposures, it was admitted the claim for recognition of the camera as a military adjunct was fully supported.

It was recommended that the plates or films should be specially

manufactured to stand extremes of heat and cold, and concentrated developers that can be used several times over be employed. Very few dishes need be taken, two, probably, being enough, one for developing and one for fixing.

The paper, as before mentioned, recommended is bromide, for it can be used while the negative is still wet, and when thus used no printing frame is required. The printing, being by artificial light, can be done at night.

It was found that, by lining a military tent with blue material, developing could be well performed by moonlight.

A bucket of water would be required, and for very rapid work the negatives need only be washed for a few minutes, and, after the prints are taken off, providing they are washed for three or four minutes, they will retain their colour for several days. A washing of two hours makes them, of course, permanent; and, when the negatives are required for future use, they should be subjected to the usual washing after the prints immediately required have been taken off. Clearing solution would be used, but no toning is necessary for the prints.

For surveying by photography it is necessary to measure a base line. Take magnetic bearings, and photograph the objects from each end of the base, taking care to level the camera each time, and to observe and record the magnetic bearings of the axis of the lens. By a mechanical arrangement in the camera, the horizontal line and a vertical line, representing the vertical plane, are marked on the negative, and consequently appear in the print. The point where these two lines cross is called in perspective the "principal point," and should agree with the axis of the lens.

The focal length of the lens must be known, and this is equivalent to the distance between the point of sight and the principal point. If we photograph a range of hills, and we wish to plot them on the paper, we draw perpendiculars from, say, the two highest points down to the horizontal line. We then plot the base on the paper, and from each end of the base we draw a line having the bearing (recorded), in each instance as the bearing of the axis of the lens, making each of these lines equal in length to the focal length of the lens; at the ends of these lines further from the base draw lines at right angles to represent the horizontal lines; the ends of the base will be the points of sight, and the points where the lines from the end of the base meet the horizon lines will be the principal points. We now measure on the photograph the distance from the "principal point" to the point where the several perpendiculars from the objects fall on the horizon line, and mark off similar distances from the principal points on horizon line on paper. If we join the end of the base with the points so marked on the horizon lines, we shall be drawing the bearing of the objects from each end of the base, and shall thus be able to fix their relative positions by intersection.

In a similar manner, by the application of this method, we can ascertain height of objects represented on the photograph. This description merely gives the outline of the method by which surveys can be rapidly executed and the triangulation carried out. Lieutenant Reed, United States' Army, has given very considerable attention to this subject, and has published a work on the subject entitled *Photography applied to Surveying.*

It will be, of course, apparent how useful photography will be in time of war if balloons are employed, and also for the reproduction of maps, sketches, or even despatches or instructions, supposing, for the sake of future reference or multiplication, it became necessary and no mechanical process was available.

For measuring the base line, a simple range-finder, such as the "Labbez telemeter," would be invaluable, as it gives ranges at sight in any measurement, and a good prismatic compass, or a Verner's complete sketching instrument, would assist in recording bearings, and the latter for plotting same, and showing vertical as well as horizontal angles.

G. R. Baker.

THE CAMERA AND THE CONVENTION: OR PICTURESQUE SCOTLAND AND PHOTOGRAPHY.

IV.

Crieff and Drummond Castle.

Being now at Callander, before going further west, we might take a run to Crieff for a couple of days. Its surroundings are rich in lovely spots with scenery of such a nature as lends itself to the production of good photographic work. From Callander to Crieff is within an hour and a half's railway journey. Drummond Castle is one of the most prominent points of interest there. We had to get a permit to be allowed to photograph at the Castle. Mr. Curr who was the factor on the estate when we were there (and likely is now) granted us permission with great pleasure

The avenue, garden, and castle are all composed of material for much good work. The garden is a little too trim and formal perhaps, there being a tendency to map it out into designs and patterns, that produces a considerable stiffness in the pictures; but the outside grounds quite make up for any deficiency in this part of the policies. When visiting the Castle we showed our pass to Donald, the Highland custodian; he remarked, "You did not need no pass, I would have let you photograph whatever you pleased." We wanted to have a cabinet bust of this old Highland worthy, he is so well known all round the country side, but thought we had no chance the morning we were there, he was so busy showing a lot of visitors round the exhibition part of the Castle, but remarked in passing, "Some other day, Donald, when we come again, we would like to make a picture of you; we would have done it now but see you are too busy."

"Na, na, I am not too pisy," he replied, "I will be with you in one minute." The bait was evidently tempting, for those visitors were off the premises in an incredibly short space of time, and Donald was with us in his full Highland garb ready to be taken. We got some good pictures of him, and sent him copies which pleased him highly.

Ochertyae.

Then there is Ochtertyre, about a mile and a half from Crieff, the grounds of which are generously open to the public at all times. It is the seat of Sir P. Keith Murray.

The use of the camera is not forbidden in these grounds, and the blending of wood and water is very charming, producing pictures at every turn.

There is a loch in the centre of the park, where boats are supplied to the visitors free of charge.

Water lilies were growing in patches every here and there, and swans in great numbers were gracing the surface of this loch at the time of our visit.

Within a radius of three miles there are two or three waterfalls, wild enough and picturesque enough to well repay a day spent amongst them. The most prominent falls are Spout Hoich and Barvie; and, for streams, there are the Turret, the Keltie, and the Shaggie, all possessing considerable interest and beauty.

Comrie.

If the stay at Crieff extend for a day or two, places of photographic interest will be found all round. The village of Comrie lies some six miles further on, on the north bank of the Earn. This small town can be reached by two roads, equally picturesque. The one passes the grounds of Ochtertyre, and the other is by the foot of the town. Comrie is a village famed for its earthquakes. It is a quiet, sleepy place, looking as if it would be none the worse of an earthquake now and again, just to shake it into life. After exposing a few plates here, another drive of six miles brings us to St. Fillans, which is situated at the foot of Loch Earn. You will remember, when going up the Oban line, we touched at the head of this loch. The other end, which we have now reached, is equally beautiful, and there is no lack of pictures to be taken—as long as your plates hold out.

And now we had better retrace our steps, and start again from Callander.

Lake of Monteith.

The next outing should be to the Lake of Monteith. On leaving Callander for Loch Venachar, you will remember we turned to the right at the end of Bridge-street; on this occasion we turn to the left, keeping the river Teith on our left hand the first two or three miles of the way. The drive to the Lake of Montelth from Callander is about six miles. On the first part of the way, for a mile or two, the Teith is fairly near the road. It is profusely wooded, and gives opportunity for considerable choice of subject. But after this we have to strike over the hill to the right, and for some three miles on there is not much of importance photographically, the hills being bare and heathery, no trees nor foliage of any kind until we reach within a mile of the loch, when a glorious view bursts upon us as we reach the incline of the hill. A fruitful valley surrounded by hills, where the village and the lake lie basking in the summer sun, the church spire peeping up from amongst the trees, the hotel nestling amongst the foliage by the margin of the lake, while in the distance the island of Inchmahome lies sleeping midst the rippling waters that surround it.

The Isle of Rest.

The Port and Lake of Monteith are of peculiar historical interest, for at Inchmahome (the Isle of Rest) Mary Queen of Scots spent some of the earlier years of her life, and it was to this place that her mother sent the four Marys to be her companions, to help to brighten up so quiet and secluded a home.

This island is the chief attraction of the place, and here stand the ruins of that monastic institution where Mary dwelt. The ruins are well arranged for pictures, with windows and doors in and about, that are just in a perfect state to please the enthusiast who revels in the ruins of the architectural work which in its slow decay still keeps telling us the story of the past. And for those who look at the matter from a more romantic point of view there will be found the hawthorn that Mary planted, and the summer-house where she sat, which are shown as objects closely associated with the pleasures of the girl queen. Many artistic bits will be found on this island quite free from the ruins.

Boats to convey you to the island can be had at the hotel, and a row of twenty minutes will take you there. The village itself is small, but very pretty, and many charming studies are to be met with without the trouble of seeking for them.

Aberfoyle.

Leaving Monteith, and driving on for other six miles, we arrive at Aberfoyle, the spot so intimately associated with Scott's Rob Roy—a spot that has been visited again and again by all sorts and conditions of photographers. And we have never been able to discover why so many people go to this place from a picture-taking point of view.

It is rich in story, certainly, but very poor in scenic effect; and we feel that the land of the McGregors at this spot is not inviting, and in the clachan they have taken to building houses, and that of such a *poor-house* type that it tends to make the place look worse than ever.

Of course, the Bailie's poker still hangs to the tree at the side of the hotel—but one can't make a picture of that—and the bridge close to the hotel has been photographed by everybody, and at the best it is not much. Upon the hill at the back of the hotel there is a little row of thatched-roofed, dry-stone-built cottages, that make a good picture with the auld kail-yard situated at the end, surrounded by the broken-down dry-stone dyke—all broken down and filled with thorn bushes in parts—a kind of unkempt decay that helps up a picture wonderfully.

Loch Ard.

Leaving the Aberfoyle Hotel, we take the road to Loch Ard, which lies in front about two miles further on.

On the way there will be found one or two typical cottages of the "White-Wand-at-the-door" class; and it is worth having a peep at the interior of one of these, for it will at once explain why Major Galbraith and his Highland friends raised such an objection to have the Baillie and Francis forced upon them when they by custom had engaged the house, for really the smallest company would fully *occupie* the place.

To the left on this road to the loch is an old mill with a broad wood water-wheel, and a little waterfall alongside of it, which makes a good picture. Loch Ard itself is worthy of a visit. Along its banks many picturesque bits are easily obtained. When we visited this spot, we had no boat, and felt the want of it very much, for it would have helped us considerably in breaking up the expanse of water in some of the pictures we took.

From Aberfoyle there is a route to Loch Katrine over the mountains by coach; it is some four or five miles' journey. This hill road is interesting for slate quarries, Rob Roy's Well, &c., but there is really nothing of any photographic interest till taking the downward turn of the hill on the forther side, when all at once the wild profusion of beauties that grace the Trossachs Valley unfold themselves to view—a scene so bewilderingly grand that will never be forgotten. But we will take the Trossachs from the Callender side, and pass through those scenes we only view from the distance here.

This hill journey was the one taken by one of the trips at the Glasgow Convention, and a very good day we had of it then.

The Trossachs.

Leaving Callander for the Trossachs, at the turn of the road we cross the Leny, with Benledi lying to the north. On the left, across the Teith, stands the Hydropathic, which looks well in the distance, set in foliage of many different tints. Near to the road, as we drive along, we come to Coilantogle Farm, where, in front, at the foot of the hill, is Coilantogle Ford. This spot we visited on a previous trip. The view of Loch Venachar is now much better seen from the high road. The hillside overlooking the loch is Lanrick Mead, which was the gathering ground of Clan Alpine. The drive to the entrance to the Trossachs proper is some seven miles, and about two miles from there to Loch Katrine. For some five miles of the way the shaggy heath and rocky, ferned mountain-side pretty well hold their own, with spots of Lady of the Lake interest every here and there; but for our purpose specially it is where Glenfinlas turns to the right that the fir-clad hills, and surging streams, and tangled copse, and rocky rivulets crowd upon us from every side, and, if it be caught in sunshine, the glory of it will fill the eye with beauty and the soul with admiration.

Then come we to the Brigg of Turk, and, keeping along the margin of Loch Achray, we shortly reach the Trossachs Hotel, a building that, in its architectural construction, blends well with its surroundings. Going or coming, the coaches wait at the Trossachs Hotel for half an hour, ostensibly to give the tourist an opportunity of lunching or dining; but, as there are many places where refreshments may be had, to the photographer who wishes to go straight on, this little wait gives him the chance of taking a few negatives, and the hotel lies in the very centre of beautiful pictures. The walk from the hotel down to the margin of the lake cannot be surpassed for beauty and magnificence, with Ben A'an towering away towards the north, and Benvenue rising skyward in the front; the boat-house and rustic pier at length come into view, with the loch itself stretching out, with thousands of shimmering reflections playing upon its surface,—

> "With promontory, creek, and bay,
> And islands that, empurpled bright,
> Float amid the livelier light,
> And mountains, that like giants stand,
> To sentinel enchanted land."

To all who are familiar with the Trossachs it will be well understood that a week could be spent there with both pleasure and profit; but, for those whose time is limited, we note the following as the spots the most popular: "The Pier and Boathouse," "Where twines the Path," "Ellen's Isle," "Silver Strand," "The Path by the Loch," with an endless panorama of pictures between, composed of scenery that Scott himself said that he presumed in attempting to describe it—scenery that, when once seen, will never be forgotten.

FIXATION OF SILVER PRINTS.

[London and Provincial Photographic Association.]

I have your letter asking for my opinion as to the best method of ascertaining the period when a silver print may be considered to be completely fixed. I remember making some experiments in this direction some time ago, but unfortunately cannot lay my hands on my notes at the present moment. However, I think I can recall them to mind pretty accurately.

The method generally recommended in the text books is, to examine the print by a transmitted light and see whether all patches or blotches have disappeared, but I cannot regard this as at all a satisfactory way. It is true that with paper of light weight, say the ordinary "Rives," the action of the hypo on the silver chloride is discernible, the proof behaving somewhat like an ordinary negative, but is of course much feebler in appearance. In fact, so feeble is the opacity, that if the paper is at all thick it is difficult to follow the action of the hypo even when designedly applied locally, and with really thick papers it is quite impossible, especially as many of these papers will be found to have in them patches of coagulated sizing that would entirely mislead one. Although, therefore, an instructive experiment, I regard the transmitted-light test as of no practical value whatever. In fact, the aspect of the print by reflected light is equally as good a test, as the surface colour of the print will at once change under the action of hypo. Of course, I am aware that this change is entirely on the surface, and therefore only shows the difference between the action of hypo and no hypo, but this is exactly what the transmitted test does also; the difference is so feeble that it is really only between those parts that have been touched with hypo and those that have not that there is any distinction marked enough to be of use. Now, tests such as these are, of course, of no value whatever, as fixing a print depends not only on dissolving out the silver chloride, but at the same time in also dissolving by an excess of hypo the hyposulphite of silver formed in the print, and this salt being in solution is of course quite indiscernible either by reflected or transmitted light. And this hyposulphite of silver is unfortunately the very point that causes all the damage in non-fixed negatives, as this insoluble salt rapidly splits up and forms a silver sulphide, the characteristic yellowy brown stain giving the print the appearance of having been scorched, as is probably too well known to all photographers.

The proper fixation of our prints is, however, so important a matter, that some experimenting in this direction might well be undertaken. I cannot now remember whether I actually did carry out the experiment, or whether I merely intended to; but my idea was to utilise the well-known test for ascertaining whether paper is properly sensitised (that is, the application of a solution of bichromate

of potash to the back of the print), for the similar task of discovering whether there was any silver left in it after fixing; the action, of course, being the formation of the highly coloured chromate of silver. One of the sulphurets of ammonium or potassium might also be used, in this case forming locally the same silver sulphide; that, allowed to form all over the improperly fixed print, eventually destroys it; indeed, it is not improbable that any acid solution applied to the unfixed print would decompose the silver hyposulphite sufficiently to form the brown silver sulphuret. But, nevertheless, although interesting as experiments, I cannot look on such tests as ever being of practical value. As a rule, they either act too completely, and show traces that would be in practice quite innocuous, or else they act too coarsely; in addition to this, they only show the condition of the one particular spot to which they are applied, unless, of course, the whole print is submerged, in which case the test is something like striking the whole of a box of matches to see whether they are good or not, or rubbing writing to see whether it is dry. Applied to the edges of a print, as such a test naturally would be, it might give quite misleading results, as I find that the most frequent cause of imperfect fixation arises from the prints clinging together in the bath, and thus preventing the hypo getting all round them. In such a case it is perfectly obvious that a test applied to the edges would give entirely erroneous results, and it is for this reason that, in practice, I never by any chance make use of them.

However, the necessity of perfect fixing is so important, that in practice I take great care in this operation, making assurance sure by always passing the prints through a second and fresh bath of hypo. For the amateur who is only printing at intervals, and who therefore does not keep a stock bath, there is no better way, and it ensures, if the bath is freshly made up, the presence of a sufficient quantity of hypo in the print; but with the professional, who keeps a stock bath continually going, the fact alone of leaving the prints a sufficient time in the bath is not sufficient, as it may very well happen that such a bath has become quite exhausted without his perceiving it. But, in the case of this gentleman, it would evidently be quite impracticable for him to test each separate print by any of the former methods mentioned, and he would have really to rely on a test proof, so that, even if he did take this trouble, he would by no means be certain that it ensured the fixation of his prints as thoroughly as he desired.

However, as I do not believe in the practical value of any of the above tests, except, of course, as a scientific experiment, I should give it as my opinion that the most practical method of ensuring perfect fixation is to carry on the fixing for a specified time, turning the prints over once or twice during the operation, and, in the case of a stock bath, taking the very simple precaution of ascertaining that the hypo is in an active state. As a matter of fact, this can be done continuously and without any preparation, by simply watching the aspect of the proofs as they are placed in the bath. If the hypo is active, as every one is aware, they will at once change colour, turning of a much redder colour (owing, of course, to the dissolving out of the soluble blue sub chloride), and the rate at which this change goes on will give a rough indication of the working power of the hypo. The proof is neither delicate nor conclusive, but if the print does not change colour or does so very slowly, it is a gentle hint to the operator to refresh his hypo bath. Of course, in those cases where it is customary to treat the prints with salt before fixing, and where, therefore, the change of colour in the hypo is very slight or entirely absent, the usually recommended test of looking through the print may be reverted to, and the result will be more certain if a small piece of uniformly exposed paper, such as a slip off the trimmings of the prints, be used. In this case, if the surface be not too solarised, there is no difficulty in seeing the line of demarcation between the fixed and unfixed portions either by reflected or transmitted light. To those who may desire a more accurate and scientific method, I would suggest a careful measurement by means of a graduated pipette of the amount of silver chloride that the hypo under examination could dissolve.

I would like here to mention one point that I have noticed in fixing prints, and that is, that if strong, or, indeed, weak hypo be applied locally the print will show a difference in opacity and also in surface colour at these spots, and these marks will be found to be irremovable, even after a lengthy immersion in strong hypo. I do not know whether these spots represent insoluble portions, or whether it is merely a sort of coagulation of the albumen at these points, but would mark the fact as worthy of some future investigation.

I am afraid that I shall not have been able to add much new light to the question at present before your Society, but owing to the press of other business, I have been entirely out of photography for some time back, and therefore find some difficulty in furbishing up my memory and notes of former experiments. LYONEL CLARK.

RATIO OF GRADATION.

I HAVE read with much interest Messrs. Hurter & Driffield's last communication, and beg to thank them for correcting some misunderstandings of mine. On reading their paper again, I find I assumed too hastily that possible loss of energy, in the form of heat, &c., had not been considered by them. In describing e as the amount of energy necessary "to change one particle of silver," I had certainly fully understood them to refer to the visible grains, and not to the particles of very much lesser magnitude which, as now explained, they had in mind. It is very useful to have this correction, as it presents a very different view of their reasoning from that which I had taken of it, and very probably some others of their readers may have gone similarly astray.

I now beg to draw the attention of Messrs. Hurter & Driffield to some misunderstandings on their part. I will first mention that I am described as holding the almost ridiculous opinion that no light capable of affecting a photographic plate will ever escape at the back, and Messrs. Hurter & Driffield kindly give me details of experiments which they invite me to repeat in order to be convinced of the falseness of such views. I have tried the experiments suggested, although it was scarcely necessary, and find, what of course every one would expect, that a sensitive plate exposed behind another, after a full exposure, will receive a considerable impression; but, if the exposure is only sufficient to produce a *small density* on the front plate, then no visible image can be developed on the other, so that, in the latter case, greater thickness of film in the front plate would have led to no greater density in the image. This Messrs. Hurter & Driffield will find, if they will kindly look through my article again, is all that I asserted. I do not, however, rely much on that fact, as, since writing, I have been studying the "correct formula" again, and find that the difference in calculated results for small densities produced by increasing "O" to any extent is very trifling unless an exceptionally thin film be considered. The charges of shifting my ground and wandering from the point, like the one I have just dealt with, are hardly, I think, justified. In my first letter I referred to an article of Mr. Plener's, in which I may mention he, in writing on the subject of sensitometer screens, gave *two* formulæ as applying to the relation between the amount of colouring matter present and the transparency resulting. The first (altering the symbols) was $T=\epsilon^{-x}$, which he considered to be correct in those cases where the thickness of the film varied proportionately with the colouring matter, and the other, which (in a simplified form) is the one I have previously given, he showed applied when the thickness of film was always constant, and only the amount of colouring matter contained in it was varied. That he was perfectly right in those views is still my opinion. The formula which had been adopted by Messrs. Hurter & Driffield to explain the relation between silver and transparency in photographic plates was identical with the first, but I was then of opinion that the conditions were such that the other was the more nearly correct, although, at the same time, I thought it was very doubtful whether either was to be depended on. My object was, in fact, chiefly to express doubt as to the one adopted. In my second letter I repeated my doubts, and described an experiment of Captain Abney's which appeared to be quite at variance with either formula.

This experiment I mentioned incidentally gave results quite in accordance with the "law of error," but I did not then advocate that formula, although I think it always deserves serious consideration, and only mentioned it in connexion with the question under discussion, viz., the relation between the amount of silver and transparency. Since that letter I have admittedly shifted my ground and introduced new matter, but still that has been to the point, as I have shown, by that means, why I now see reason to believe that the formula, $T=\epsilon^{-x}$, has, after all, been correctly made use of. On the whole, I think there has been very little to complain of in this respect. I ought, perhaps, to have noticed Messrs. Hurter & Driffield's kind offer to test any plates I could send them which I thought likely to give different results from those calculated by their formula, but I took it as a standing offer of which I might avail myself at any future time, although I scarcely expected to be able to do so, as I was not willing to trouble them unless I considered that there was a definite prospect of settling some doubtful point in that manner. The remark that I had "not *again* mentioned the subject" may, however, have led some readers into the mistaken impression that I had undertaken to supply such plates.

Messrs. Hurter & Driffield's explanation as to the true meaning of dx does not, I think, remove all possible objections to the reasoning on which the "correct formula" is based. They will probably admit, as I believe it is the opinion of most previous experimenters, that the visible (more or less) grain must be considered as a whole, and that, however some of the molecules in it may be affected by the action of

light, it will not be developable till it has received a certain amount of exposure, after which *all* the Ag Br contained in it will be reduced on development. If that be true, there must always be in an exposed plate a certain amount of unchanged Ag Br which has absorbed energy, but which will contribute nothing to the density of the developed image, and the energy so wasted does not appear to be in any way accounted for in the demonstration of the "correct formula." Another matter to be considered as a probable source of error is the fact, that in every emulsion there is, of course, always considerable variation in the sensitiveness of different particles of Ag Br, but the "correct formula" treats them as being all alike.

Messrs. Hurter & Driffield consider that my reasoning in attempting to show the superiority of the shorter formula, involves assumptions which are directly opposed to experimental facts, and complain that I do not supplement that reasoning by giving instances of experiments which support it. Not having conveniences for photometrical observations, I cannot do so at present in a very satisfactory manner, but I may surely be allowed to make use of the valuable material which Messrs. Hurter & Driffield have themselves supplied in the account of their investigations; and, if I can show that those experiments do not establish all that they are supposed to, I am perhaps offering useful criticism in pointing that out. In the absence of experimental proof that the simpler formula gives the more truthful account of the action of light in photography, Messrs. Hurter & Driffield decline to consider the reasoning which has led me to prefer it. Now, the experiments on which I rely are those described by themselves. In their original paper they mentioned that they had measured the densities, falling within the "period of correct exposure," in dozens of plates, and found them all conform to that formula. Now, however, it is explained, there is not a plate in the market to which it applies, except as a rough approximation; but, in opposition to that opinion, I will quote an experiment, viz., No. 21 in the paper on "Photo-chemical Investigations," which is perhaps the most important of the series. In the following table I give Messrs. Hurter & Driffield's observed densities—those calculated by them by the "correct formula" and the figures which would result by the shorter one if C = ·74 and γ = ·87.

Exposure C.M.S.	Density found.	Density calculated. "Correct" formula.	Density calculated. Short formula.	Exposure C.M.S.	Density found.	Density calculated. "Correct" formula.	Density calculated. Short formula.
10	·250	·339	·226	320	1·535	1·531	1·536
20	·460	·520	·488	640	1·885	1·780	1·797
40	·755	·743	·750	1280	2·088	2·022	2·059
80	1·010	·992	1·012	2560	2·262	2·218	2·321
160	1·270	1·272	1·274				

It will be seen that the results by the short formula are at least as accurate as those by the other. This table includes all the "period of correct exposure;" we know, of course, that it is only during that stage that it applies, and I have endeavoured to account for that fact in my last article. We have here two formulæ, each of which gives calculated densities nearly corresponding with those found by experiment, but only one can be theoretically true, and it seems fair matter for discussion to attempt to decide which is really the approximate formula, and which, if either, the correct one. I think most photographers will be glad to know that Messrs. Hurter & Driffield are continuing their valuable experiments, and it is to be hoped that one result of their future investigations may be to throw more light on theoretical photography; perhaps by clearly demonstrating the truth of the "correct formula," but possibly by discovering some still more satisfactory explanation of the photographic action of light.

H. J. Channon.

PROJECTIONS IN NATURAL COLOURS.

The visit of Mr. F. E. Ives to this country for the purpose of lecturing at the Royal Institution and demonstrating his method of reproducing natural colours upon the screen is attracting public attention to the possibilities of colour photography.

The writer has himself experimented during the past two summers in this direction, and his efforts were so successful that a British patent was completed, in order to cover his improvements upon earlier methods. It should be understood that Mr. Ives had worked in colour projection for years before this patent (No. 19402, November 20, 1890) was applied for, but his system was of so difficult a nature that little progress was made; and, in fact, Mr. Ives once stated, several years ago, that, after the most strenuous exertions, he had only succeeded in making *one* satisfactory set of three slides which, when displayed upon the screen, represented a landscape with natural colours.

Mr. Ives' system, at that time, was to make three negatives of each subject on three separate glasses, using certain colour screens to sift the light. These three negatives were printed from in the ordinary manner, so as to make *three* lantern slides on three separate glasses. Finally, three lanterns, with three limelights, were employed to project the three slides simultaneously upon the screen, with the aid of coloured glasses; so that, when accurately super-imposed, the desired composite image was obtained upon the screen.

The above paragraph represents the full amount of knowledge possessed by the writer when he first took up the subject. Starting with red, yellow, and blue as the primary colours, he soon found that it was not possible to reproduce colours correctly with them; and eventually he adopted red, green, blue, and violet as his primaries. With these, all colours could be reproduced; but, in working from nature, there is usually so little difference between the blue and violet sections that it is doubtful whether it is not better to combine the two sections into one, blue-violet. Thus, working independently, it will be seen that the writer has proved that the three primary colours, red, green, and blue-violet, which Mr. Ives was then, and is still, using, are practically the best.

The improvements which the writer made in Ives' process were as follows:—Instead of producing the negatives on three separate glasses, they were put upon a *single* glass by a special camera, furnished with colour screen; and thus, instead of three negatives to be developed, there was only one compound negative. Further, the three positives were also put upon one glass, by the simple device of printing by contact from the compound negative. It will thus be seen that, instead of using a minimum number of six plates to produce one set of positives, the same result was effected with *two* sensitive plates, one for the three negatives, and one for the three positives. Further, again, the three positives on the one glass were not separated, but were put as a whole into a small special lantern with *one* limelight; thus the difficulty of maintaining three separate limelights of equal power in a large triple lantern was overcome. The special lantern differed from the ordinary lantern chiefly in that it had several object lenses, or their equivalent, instead of one.

The above improvements were duly patented, and were first published in detail in The British Journal of Photography of January 9, 1891. A public demonstration of about twenty pictures made by this process was also given on May 14 of the same year before the Manchester Photographic Society, which was considered very successful. The *Manchester Guardian* of May 16, after describing the apparatus, stated:—

"The subjects shown were varied in character, including landscapes, sunsets, shop windows, and advertising hoardings. The skies, with light, fleecy clouds in broad daylight, or heavy masses of brilliant colour in the sunrises, were beautifully shown, and the coloured posting bills on a hoarding, as affording a means of analysing the effect of each colour screen, were even more interesting than the landscapes or the more important subjects."

Similar reports were given in many other papers, both British and American.

In June, 1891, six months after the publication of the writer's improvements, Mr. Ives gave a demonstration before the Franklin Institute of "some recent improvements he had made in the means of operating the process, by which it was rendered comparatively simple and reliable, and capable of immediately profitable commercial operation for lantern illustrations." The new arrangement included several features similar to the improvements for which the writer had obtained a British patent. In short, Mr. Ives now makes his three negatives on one glass; his three positives on one glass; and displays them by a special lantern with one light. It is this system which has helped Mr. Ives to produce the views, stated to be of great beauty, which he is now exhibiting in England.

The arrangement of the lenses in both camera and lantern can be varied in many ways without departing from the principle, and Mr. Ives has undoubted priority in several features of his system, such as the selection of the colour screens, the arrangement of a camera for taking three separate views of one object simultaneously from the same point of view, and an appliance called the helio-chromoscope for viewing the slides direct, without the aid of the lantern.

There can be little doubt that Ives' colour system will be further developed and improved in the near future, and that it will eventually assume an important position in lantern projection.

Albert W. Scott.

THE WARWICKSHIRE SURVEY.

The Exhibition of Photographs of the Survey of Warwickshire, now on view in the Municipal Art Gallery, Birmingham, is well worthy of a visit, and does great credit to the promoters of the object in view. On the 14th inst. was handed over to the city of Birmingham, through the Mayor, by the President of the Photographic Survey, J. B. Stone, Esq., about 1000 photographs in platinotype to be placed in the Free Library for reference at all times. These will form the nucleus for an ever-increasing collection of all that is interesting in the county, forming a reliable record for posterity of the buildings ancient and modern, monuments and manners, scenery and society, and other facts as they now exist. The Midland metropolis may thank Mr. W. Jerome Harrrison for his unwearied advocacy at all times and in all places of a systematic "survey" being made, and especially for his repeated appeals to the Birmingham Photographic Society to undertake that of their own county. How far and how well they have already carried out his suggestions will be seen in a visit to the Art Gallery, where above 600 of the views sent in are shown.

Having been invited as a contributor of some of my Convention views to the collection, I attended the presentation, and had an opportunity of seeing the pictures. It is not to be expected that a collection got together for such a purpose as this could compete with an ordinary photographic exhibition, either in art, quality, or technique, yet a great number of the exhibits would rank high, even if judged by these standards; such, for instance, as the fine interiors of Castle Bromwich Hall and the ancient tomb in Seckington Church, by E. C. Middleton; the Offchurch and Compton Wingate's Views, by Longmore, Simpkins, and others; *Grimshaw House*, by S. G. Mason; two sweet little cottage scenes at Hampton Lucy, and a View of Arbury Hall, by J. H. Pickard; the Baddesley Clinton Views, by Harold Baker and others; some capital work by E. H. Jacques and several others whose names I forget and cannot supply from the catalogue, which is good in every other respect, being well printed, and consisting of eighty-four pages of excellent matter, both historical and descriptive; but the names of the photographers are not given, neither can I remember a tithe of the views worth naming, for there is a delightful jumble of old fonts, church porches, tombs, castles, halls, cottages, rivers, and lanes, which form an ever-shifting scene in one's memory. Most of the views are on half and whole-plates, a few quarter-plates and about a score, presented by the President, 17 × 13 size, taken on wet plates in 1868. The day was finished by a garden party at Mr. Stone's, at Erdington, where a large photographic group was taken, and, in the evening, a dinner at the Colonnade Hotel.

Not being satisfied with photographs alone, I stayed a few days with a friend in "woody Warwickshire," some eight or ten miles from Birmingham, and enjoyed, as much as I could without my camera, visiting some of the places around—Solihull, Knowle, Packwood, Lapworth, Hampton-in-Arden, Henley-in-Arden, Berkswell, and places whose names I cannot recall. We had delightful drives along the lovely lanes, tree-shaded, with grassy borders and flower-besprinkled banks on either side, where bloomed amid the tangle and tufts of grass many a sweet primrose and purple hyacinth, with patches of red lychnis and the star-like flowers of stitchwort; past many a picturesque half-timbered farm-house and cottage, with blossoming orchards and gardens; under bending boughs of graceful trees, in all the fresh beauty of their varied spring attire; over bridges, giving glimpses of water-meadows, fringed with elder and willow—pictures everywhere! not to mention the old churches we visited.

Truly, the Birmingham Photographic Society has undertaken an herculean, if a pleasant, task. Even in the small section of the county we traversed there is plenty to be done. Take Berkswell, for instance; leave out the Holl, if you like, and confine yourself to the village proper, all comprised in a few acres, where you could revel for a couple of days in getting pretty pictures. It is an old-world, out-of-the-way sort of "Sleepy Hollow," with a most interesting Norman church. You may be sure it *is* Norman, if you are not up in architecture, for the old woman who keeps the keys said it was "bordering on 800 years." Singularly enough, the same authority told us the parson's screw also "bordered on 800 —— pounds!" Near by is the well, from which this ancient place is named, with a wonderful supply of clear water. The village stocks stand perfect on a triangular patch of grass in the centre of the village, shadowed by ancient elms. Why there are *five* holes to accommodate five ankles I cannot tell, but suppose, if three delinquents were captured at one fell swoop, one of them would have to be content to rest one leg only in the oak! But these stocks, though in good working order, are never used now; they belong to the good old times, and recall Hogarth's pictures in Butler's *Hudibras*, and the pleasanter recollections of dear old Riccabocca in Bulwer's *My Novel*. There are thatched cottages you could not pass by with a camera, and a picturesque old inn with a sign showing the "Bear and Ragged Staff," the cognisance of the Earls of Leicester, and a ship's gun in the front garden taken at Kertch. We had some mutton chops at that inn, and found the landlord was a professional photographer. I expect Bank and other holidays bring lots of people here for a drive from Birmingham and Coventry, for "groups are taken," I suppose, in the stable-yard and pretty back garden. Thank goodness, the place was quiet enough during our visit, and not a soul to be seen, or a sound to be heard save the cawing of rooks and the droning hum of the school near the church. Ah, that church is a dream, a poem in architecture! I will not inflict on you any attempt at discipline, but cut short my rhapsody with recommending "where to go with the camera"—Warwickshire, supposing you are satisfied with sylvan scenery, pretty cottages, old churches, moated houses, and castles. You will find all these to your heart's content. I would further advise you to send unmounted copies in platinotype of such good negatives as you may secure to the indefatigable Secretary of the Photographic Survey of the County of Warwick, J. H. Pickard, 11, Priory-road, Edgbaston, Birmingham.

Richard Keene.

GELATINO-CHLORIDE-OF-SILVER PAPER: ITS MANIPULATION.

[North Middlesex Photographic Society.]

The title of my paper, as it appears upon our calendar, covers rather a wide field, and I will ask you to take what I have to say for the description of the process as I am in the habit of working it. I wish more particularly to address my remarks to beginners or to those of you, if such there be, who have not as yet done much with this particular material.

Before going into the method of working, I will briefly bring to your notice certain points connected with the history of the process, which may possibly be of interest to you, and will also mention what I consider its principal advantages.

Historical Notes and Principal Advantages.

In the year 1865 Mr. G. Wharton Simpson introduced a process of silver printing called the collodio-citro-chloride process, or Simpson-type, in which the sensitive salts were held in suspension by collodion, and from which very fine results were obtained, but owing to the favour which albumenised paper obtained, Mr. Simpson's process did not continue in very general use.

Captain Abney, in 1882, discovered and suggested the use of an emulsion of chloride of silver, citrate of silver, and gelatine for printing-out, and in 1885 the late Mr. J. B. Obernetter put upon the market his gelatine emulsion paper; Liesegang & Trapp manufactured the paper commercially in the following year, and the Blackfriars Sensitising Company introduced its manufacture into England in 1890, since which time the Ilford Company have taken up the production of printing-out paper, manufactured upon somewhat similar lines, and apparently at a considerable reduction in price. I cannot enter into the details of the manufacture of gelatino-chloride paper, but will merely say that the paper generally used has a prepared surface, and is known as baryta or chalk paper, such as is used for collotype, in which the surface is coated with an insoluble film of gelatine and barytes or other substance. The prepared paper is coated with an emulsion of gelatine and sensitive salts of silver, made much after the manner of the ordinary gelatino-bromide emulsion for plates, and applied by hand or machinery; the paper is then dried, and is ready for use. In this state we receive it, sometimes a little older than it might be. The particular advantages it possesses are, in the first place, its suitability for weak negatives. With negatives which are wanting in what is commonly called "pluck," far better results are obtainable with this than with ordinary silver paper. By the use of green glass in printing, even negatives of exceptional weakness may be made to yield quite good results upon those papers containing citrate of silver (Obernetter and aristotype are, I believe, of this description), the reason being that silver chloride and silver citrate, which enter into the composition of the emulsion, are differently affected by light—chloride of silver is principally sensitive to the ultra-violet rays, and citrate of silver to the blue rays and some distance into the green of the spectrum. Now, the citrate of silver, which is sensitive to the green rays, gives greater contrast to the resulting print than does the chloride; so, by stopping out all but the green rays, we obtain the greatest amount of contrast from the citro-chloride. There is another advantage of a similar description which citro-chloride presents, that of printing quicker in the winter-time, when the ultra-violet rays of the spectrum, to which chloride is most particularly sensitive, are very deficient. The rapidity of printing is very considerably greater at any time of the year than is the case with ordinary albumenised silver paper, like which it is particularly adapted to combination printing from two or more negatives, nothing being left to guess-work or unaided experience, as with platinotype or bromide, and, if kept dry, may remain a long time in the printing frame without apparent deterioration.

Range of Tone.

The range of tone obtainable at will is very considerable, and reds and warm browns, purples and blacks, may be obtained with certainty, pro-

vided always that the print is suitable. There is a photographic saying that the tone of a print is settled when it leaves the frame, which is, doubtless, true of most print-out processes requiring toning, but we have, I think, in this case, far greater range than with albumenised paper or other processes. The ease with which the surface of the paper can be manipulated is a particularly useful feature from an artistic point of view. We can, by roughening the surface to a certain extent, tone down the brilliancy of strong contrasts, and partly kill the painful detail and small flickering lights often so confusing in photographs, or accentuate the detail and piquancy by burnishing to almost any required degree; or, again, the surface may be left in its natural state, or just slightly dulled.

Conditions of Permanency.

Of all the qualities of a photographic printing paper, there is one which is, or ought to be, of more importance than any other, that is, the permanency of the result. We all know the unstable nature of the average silver print, and the yellow sickness which often robs it of its charms within a year or two of its production, and such of us as admire the advantages and beauties of a process which has held its own so long, in spite of inherent decay, should be glad to welcome a material of a similar kind of certainly higher capabilities, and containing the elements of vastly greater permanency. The reasons upon which the claim for greater permanency is based are these: That not only is the sensitive film composed of a definite silver compound emulsified in gelatine, whereas, in the albumenised silver paper, we have a very unstable compound, silver-albumenate, but the emulsion is spread upon a prepared surface, and is cut off from, and does not sink into, the texture of the paper. It is consequently washed with greater ease and efficiency, the disintegration of the paper and size consequent upon prolonged washing of silver prints being unquestionably a considerable factor in their destruction. It is, of course, necessary, if the most permanent results are to be obtained, that the prints should be thoroughly well fixed, the hypo effectually eliminated, and suitable boards and materials used for mounting. There are certain general rules relating to the various manipulations which must be closely attended to, or, without doubt, the results will be partial or complete failure. The ways and customs of ordinary silver printing must be put on one side, for the material is different and requires a different treatment. Care is to be exercised in handling the paper, especially when wet, as then the surface is very susceptible of injury. The hands and dishes must be clean, and the latter used always for the same purposes, whilst hypo must be carefully guarded against, as the faintest trace before or during toning will stain the prints. The storage of the paper requires careful attention, and it will then keep, for the most part, in good condition for a considerable time if the air, light, and damp are effectually excluded. The best way, I believe, to store it is under pressure. I have myself used Aristotype paper which has been kept several months, and stored for four or five weeks between printing and toning, without any appreciable sacrifice of its good qualities.

The papers to which my remarks refer are Obernetter, Aristotype, Celerotype, and Ilford, these being the only brands which I have used. Personally, I prefer the celerotype and aristotype for warm tones, and the remainder for purple or black. They all give a remarkable amount of detail, and are well packed up and sent out. The celerotype, however, does not seem to be so well selected as the other papers referred to; it has also a greater tendency to curl during the operations, but the paper is thicker, and stands more wear and tear.

Printing.

Prints are made by contact and exposure to daylight in the ordinary manner. Any negatives, excepting those of exceptional density, are suitable for the process, those of a weak character showing to proportionately greater advantage. The negative is prepared as usual for silver printing by any other process; but, above all things, if of any value, it should be varnished, or the free silver will quickly stain it beyond recognition, especially if any trace of damp be present. The silver stain may not show at the time, but I have seen it develop afterwards. Lengthened printing in the open air in winter time will bring a rich harvest of stains. In placing the paper in the frame it is always desirable to dust the negative and paper with a camel's-hair brush, as dust will leave white spots, and to have the back of the negative clean, a thick pad of blotting-paper or felt behind the paper is also very desirable. All possible care should be taken not to expose the paper to any but very dull or artificial light, as, by reason of its sensitiveness, it will rapidly become darkened. The same care must be exercised whilst examining the print, which should always be removed into a dull light before the frame is opened. Printing should never be carried out in direct sunlight, excepting with negatives of too great a density, and for any negative inclining to weakness a very subdued light will give the best result. One, two, or three thicknesses of tracing, or other translucent paper, pinned over the face of the frame will work wonders with thin negatives, especially where masking-out and printing-in of skies or other portions is resorted to. As regards the extent to which printing should be carried, it is, I think, generally desirable to continue exposure until the darkest parts become bronzed, though this may not be practicable with some negatives. The bronzing will be lost in toning and fixing, as will also a considerable amount of the depth of the print, and proper allowance (to be gained only by experience) must therefore be made for this.

Toning and Fixing.

If the toning and fixing are carried on in separate baths, greater reduction will occur than if a combined bath is used. The prints, if preserved from light and air, may be kept two or three weeks before toning, but if stored for much longer time the whites are apt to become dirty, and difficulty may be experienced. The toning or bringing of the prints to a more pleasing colour is one of the most important of the operations connected with the process, and is effected by a variety of substances, the principal being gold, uranium, or platinum in combination with other substances. It is impossible for me to wade through a list of the numerous baths recommended, for their name is legion, but will give the formulæ for a few with which my small experiments have been conducted. Speaking generally of toning, I have a strong leaning to the more rapid baths as being the most interesting to work with, something of the charm of development entering into the work as the prints visibly change colour. Daylight is undoubtedly better to tone by than artificial light, the latter requiring a considerable experience of results. The light, however, must be weak, and the prints given no unnecessary exposure to it. In all cases the tone of a print is to be judged by transmitted light, and not by reflected light, the appearance of the print in the toning bath being no sure guide to the tone when fixation is complete. For instance, Obernetter paper in a uranium toning bath will appear quite a dark purple-blue, but changes almost instantly to brown when placed in the hypo. The tone must consequently be judged by looking through the print at the source of light. The changes of colour made by prints in some of the toning baths is very striking, brilliant yellow, red, claret, purple, and blue often succeeding each other. Cleanliness cannot be too much insisted upon at all times, but more especially during the operation of toning, especially where separate toning and fixing baths are used simultaneously. In the instructions given with the aristotype paper, the printer is directed to use one hand only for the toning bath and the other only for the fixing, transferring the prints as toned from one hand to the other; and, if this method is carried out, the chances of stained prints are greatly reduced, the faintest trace of hypo from fingers or other sources being sufficient to discolour the print. The toning bath must, in nearly all cases, be preceded by a thorough removal of the soluble silver by washing in several changes of water for from ten to fifteen minutes, the prints being placed in the water face downwards, else a deposit is liable to form upon the face. The first washing water is seen to rapidly become discoloured. The first wash of water is best poured off as quickly as possible, as it has the effect of degrading the whites if allowed to remain in contact with the prints; in the after-washing, however, the water may remain unchanged for a longer time. Some toning baths will require the prints to have less preparatory washing, and I note that the instructions issued with the celerotype state that one good washing is sufficient, and that the paper contains no free silver.

Gold Toning.

Toning with gold may be roughly divided into two methods—the first where the toning and fixing baths are kept separate, and the second, where the toning and fixing are carried out in the same bath and at one operation. There is, I think, no doubt that the first method is the best and the most certain, and the chances of permanency much greater, but it involves a little more trouble. I may here draw attention to the defects of the combined baths. Probable want of permanency in the print owing to the exhaustion or partial exhaustion of the hypo, the bath continuing to tone but fixing imperfectly, the latter being, of course, the most important operation. Then, again, many combined baths have alum in their composition, and the mixture of this with hypo causes a deposit of sulphur and oxide of aluminium and the liberation of sulphurous acid, leading, in all probability, to fading and degraded prints. The alum is used to arrest the disintegration of the gelatine by the sulphocyanide, and to ensure the regularity of toning.

Formulæ.

Turning now to the gold bath—for after-fixation nearly any good bath may be used—that given with the aristotype paper I have always found to work well,—

A.

Water	2 ounces.
Chloride of gold	2 grains.

B.

Water	3 ounces.
Sulphocyanide of ammonium	30 grains.
Hypo	1 grain.

One part of A poured into one part of B, not the reverse. It is necessary to dilute this a little, say about one-third more water. The bath must not be used until the red precipitate is redissolved and quite colourless. If the hypo be omitted brown prints may be obtained. The bath recommended by Obernetter for his paper is good for purple tones and is as follows:—

A.

Sulphocyanide of ammonium	3 drachms.
Sodium hypo	5 grains.
Water to	20 ounces.

B.

Distilled water	3 ounces.
Gold chloride	15 grains.

Pour about two and a half ounces of B into A, and stir well while doing so until quite clear; then add three to six ounces of water. For reddish brown tones increase hypo to ten or fifteen grains. This bath may be kept and strengthened with gold as required. The bath recommended for Ilford paper is as good as any and very simple.

Water	16 ounces.
Sulphocyanide of ammonium	30 grains.
Chloride of gold	2 ,,

This bath should be kept for a day before using, and tones in five or six minutes, and the bath, when it refuses to tone, should be replenished with gold or filtered and used as a base for a new bath. A good bath for brown or sepia tones is—

1.

Water	50 ounces.
Sulphocyanide of ammonium	1 ounce.
Sat. sol. ammonium carbonate	15 to 20 drops.

2.

Water	20 ounces.
Gold chloride	1 grain.

It must not be used till quite clear. It works well with celerotype, but I have never been able to obtain satisfactory results upon Obernetter paper. For bluish-black tones, Liesegang's formula works well.

Water	25 ounces.
Sulphocyanide of ammonium	1 ounce.
Phosphate of soda	1 ,,

A few hours before toning, add to ten ounces of this solution a solution of five grains of chloride of gold in one ounce of water. After this bath has been used add some more of the gold solution; it can then be used again. And there are many other equally good baths given in the instructions issued with the various papers which it is not worth while entering upon in detail. J. C. S. MUMMERY.

(To be continued.)

BOSTON CAMERA CLUB JOINT EXHIBITION.

THE Committee having the conduct of the Fifth Annual Joint Exhibition of the New York, Philadelphia, and Boston Societies report that the Board of Judges have announced awards to the following British exhibitors:—Medals: Messrs. A. R. Dresser, Hamilton Emmons, Lyddell Sawyer (Newcastle), F. Dundas Todd (Edinburgh), Clement Williams (Halifax). Diplomas are awarded to, among others, Mr. C. Court Cole, of Oxford, Mr. I. W. Evans, of Wolverhampton, and Martin J. Harding, of Shrewsbury. We gather that the Exhibition, which was open from May 2 to 7, was a large and successful one, about 1300 pictures being shown, and the attendance on the fourth evening numbering 3000. We have received the Exhibition Catalogue, which is a sumptuous volume, enriched with several very fine photogravures and collotypes.

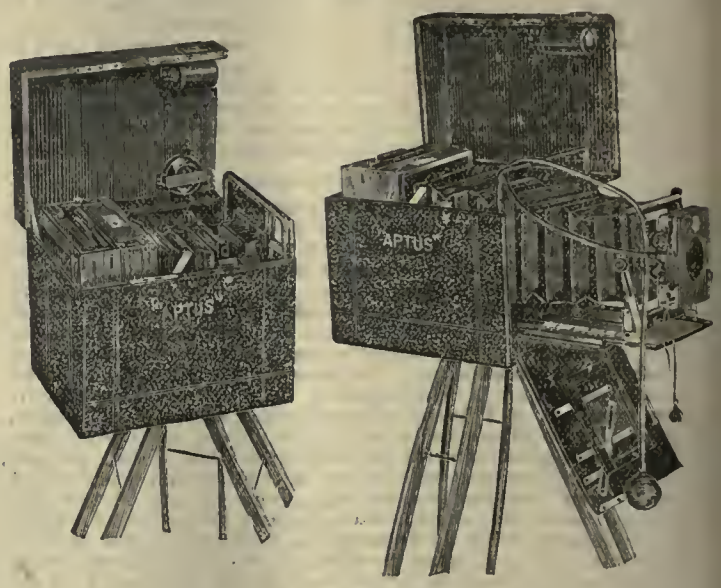
CHADWICK'S IMPROVED STEREOSCOPE.

SINCE we described the achromatic stereoscope of Mr. W. I. Chadwick, of Manchester, in last ALMANAC, its maker has considerably added to its efficiency in two respects. First, he has mounted the eyepieces on moving blocks, which, sliding horizontally, permit of such a separation of the lenses as enables the eyes to see, with stereoscopic effect, pictures that are badly trimmed and mounted in respect of being too wide apart. He has also, by means of two brass springs, provided easy means for the insertion and examination of slides, quite irrespective of the length of their mounts. These improvements render the stereoscope perfect.

THE APTUS UNIVERSAL HAND CAMERA.

THIS camera, manufactured by Messrs. Sharp & Hitchmough, Liverpool, and which has been exhibited at several London societies during the past week, enacts the *rôle* of both a hand camera and a focussing camera on a stand. When used in the former capacity, it appears as a compact leather case, having the usual perforation in front for lens and finder. The positions of the relative parts are shown in the cut, which represents it with the lid thrown open.

By releasing the front and allowing it to fall, the base-board is then capable of being drawn out, as shown in the following cut. It will be



seen that the body is capable of being distended to a considerable length, permitting the use of a lens of long focus. The various operations, such as setting and releasing the shutter, are performed from the bottom. It has, too, a swing back, and, taken altogether, it is well thought out and well made.

Meetings of Societies.

MEETINGS OF SOCIETIES FOR NEXT WEEK.

Date of Meeting.	Name of Society.	Place of Meeting.
May 30	Dundee Amateur	Asso. Studio, Nethergate, Dundee.
,, 30	Rossendale	Townsend-chambers, Rawtenstall.
,, 31	Lancaster	Storey Institute, Lancaster.
,, 31	Leith Amateur	
,, 31	Warrington	Museum, Bold-street, Warrington.
June 1	Edinburgh Photo. Society	Professional Hall, 20, George-street.
,, 1	Photographic Club	Anderton's Hotel, Fleet-street, E.C.
,, 1	Portsmouth	Y.M.C.A.-buildings, Landport.

PHOTOGRAPHIC SOCIETY OF GREAT BRITAIN.

MAY 24,—Technical Meeting, Mr. Edgar Clifton in the chair.

THE NEW CONCENTRIC LENS.

A paper, dealing with the properties of the new concentric lens of Messrs. Ross & Co., was read by Mr. H. G. Heyburn. [This will appear in a future number.] At its conclusion Mr. Heyburn described Messrs. Ross's lens-testing apparatus, a *replica* of which was on view. This consists of a fixed watch dial on a plane surface, parallel to which, at a distance of several feet, is placed a holder for lenses of various sizes. Axial to the lens is a microscope on a stand, which is adjustable to the focus of the lens and capable of lateral movement, which thus permits of a lens being examined obliquely as well as centrally, the former being facilitated by a second and movable dial which may be placed at any desired position of obliquity. The bulb is in the form of a sphere, and thus the focal distance is the same for all angles of obliquity. No distortion is produced, no matter to what position the bulb may be turned.

At the conclusion of the paper, Mr. J. Stuart presented the Society with a copy of Dr. Schroeder's book entitled *Die Elemente der Photographischen Optik*, which was the standard work on optics in Germany. It had been criticised by men of learning in Germany, including Professor Abbé, who said that its only fault was its conciseness. Dr. Schroeder distinctly states that the majority of text-books in the hands of opticians were exceedingly defective, such books sometimes only dealing with portions that were simple, and forgetting oblique pencils, and other important conditions. The optics of photography were more complicated than the optics of the telescope, where only the central pencils were dealt with. In reply to Mr. Debenham, Mr. Stuart said that the statements made in the paper were Dr. Schroeder's, who was responsible for every word contained in it.

Mr. W. E. Debenham said there were several statements in the paper which he felt inclined to dispute very strongly. In the first place it had been stated that there was no distortion with the concentric lens, on account of the radii of curvature presenting parallel tangents from a certain position, which doubtless would be the position of the diaphragm. In that case there would be no distortion if the lens were used as a single lens.

Mr. Stuart said it gave absolutely straight lines as a single lens, the Gauss points being exactly in the centre.

Mr. Debenham said that the reason given accounted for the absence of distortion. As to "depth of focus," it had here, as he gathered, been claimed not for central rays, but for marginal rays. He had always maintained that there is no lens superior to any other in depth of focus.

Mr. Stuart pointed out that the concentric lens distributed the rays equally well all over the field.

Mr. Debenham could understand that it gave better definition at the margins; and therefore, starting from a fine point, they could move the focussing screen for a greater distance without reaching a certain amount of out-of-focus effect with a lens which defined well at the marginal focus. He did not call this depth of focus, but better marginal definition. And then, as to the concentric being quicker than other lenses in which the rays were not brought perfectly to focus, while here they were all brought to a point, this was equivalent to saying that a perfectly focussed view was quicker than one out of focus, but he did not find that pictures suffered from under-exposure in the unsharp parts. He thought this claim for extra rapidity a great mistake. In reference to two diagrams on the walls, illustrating Messrs. Rom's testing method by showing that objects on a plane surface were reproduced by the lens on a plane field without distortion, while objects on a concave surface were distorted on a plane field, Mr. Debenham said it was a great mistake to suppose that the objects at the side of the concave surface should be distorted. It would be the same with this lens as with any other, and the size of the marginal objects was merely due to the perspective of near objects. He regretted very much that these claims should be made in respect of such a very fine instrument as this lens, which, for definition and flatness of field, was a great additional power in the hands of a photographer. In all cases where rapidity greater than *f*-16 was not required, it seemed to him that the lens would be more useful than any other lens which preceded it, especially in cases where a widish angle was required. It was therefore more to his regret that these claims should have been made in connexion with such a splendid instrument.

Mr. Stuart could not at all agree with the remarks of Mr. Debenham as to the rapidity of the concentric not being more than that of any other lens of the same aperture and focus. It must be apparent that, if all the rays come to a point, the picture must have more intensity. There was another reason why the concentric lens must be more rapid. Unlike an ordinary lens, it had no secondary spectrum, the two glasses being extremely crystalline. By comparing a concentric with a symmetrical, the difference would be seen at once. As to colour not being detrimental to the rapidity of a lens, he had used glass for telescopes of sp. gr. 3·65, and had found one maker's glass take about 10 per cent. off the light more than another maker's. It was not so much in photographic lenses, but it was certainly something. He had dealt with the matter practically, and had had the lenses side by side with the same stop, when the concentric gave an intense image where other images were under-exposed, the difference in favour of the former being quite 25 per cent. He was quite willing to put the lenses to the test of using them stereoscopically. If he did not prove the statements that had been made with regard to the concentric lens, he would withdraw them.

Mr. Debenham said it was not fair to put it upon him that he suggested colour made no difference. The difference between the colour of the glass in the concentric lens and a rapid symmetrical was not great; the rapid symmetrical, as Mr. Stuart knew, had not got deep yellow or green glass. What was the total loss of light from the colour in a rapid symmetrical?

Mr. F. H. Wenham said that most photographic lenses showed colour, which was the result of under-correction; nevertheless, such lenses were actinically achromatic. One of the greatest difficulties in the construction of photographic lenses was the cure of colour.

Mr. Debenham said that was not the question. What was the amount of light which was intercepted by the colour of the lens? It was generally recognised that the loss by colour was small, more light being lost by reflection from the surfaces. With regard to the concentration of the rays making the lens more rapid, this meant that, if a building were put out of focus, it would destroy its rapidity; but he did not find it so. He wished to raise a protest against the assumption that a slight amount of spherical aberration leads to loss of rapidity, owing to the light not being brought to one plane.

Mr. Wenham stated that in an ordinary lens it did not follow in all cases that the oblique pencils were indistinct. If they took a sphere with lines passing through it, they would have a concave surface with the oblique rays equally distant, struck as a radius from the centre of the lens. Cut the sphere in half and the convexity is reduced one-half. What was the consequence? They would get astigmatism of the oblique pencils appearing, and be unable to get a distinct image of the marginal rays. When a concave meniscus passed a divergent ray through it, an opposite effect took place. The marginal pencils have a much greater degree of distinctness over a concave field, and the correction was much easier. Suppose, in order to secure a concave field, they altered the curves of the lens, the nearer they approached to flatness, the more perfect the oblique pencils would be. It was a peculiar property of this lens that it would give a concave field if exaggerated, but in the proper form it gave a perfectly flat field. In an ordinary lens they got distribution of coma at the marginal pencils, like two arcs crossed, in fact, an object at the margin being narrow and distorted. He had tested several of these lenses and found what he once thought was an optical impossibility—that is, that objects at the margin of the field retained their figure perfectly.

Mr. Debenham said Mr. Wenham had spoken of the lens possibly having a concave field. When a lens gives objects which are parallel to the focussing screen, and those near the focussing screen are also in focus on the screen, and so give a flat field for those objects, must it not have a concave field for distant objects?

Mr. Wenham said, No. Take another illustration—that of a rapid portrait lens. In taking a group, a photographer would not put the persons in a straight line; he would put them in a semicircle, and get an approximately flat field. There was no occasion to do that with the concentric lens. It gave a right line from a right line, whatever the distance might be.

In answer to a question of Mr. Swift's, Mr. Stuart said that the lens was valuable for copying purposes; but, of course, *f*-16 should not be used.

Mr. Debenham said it was undoubtedly the best lens for copying purposes.

Mr. W. G. Tottem, of Messrs. G. Houghton & Son, exhibited and explained the "Shuttle" Hand Camera of that firm.

Mr. Askew exhibited a portable lantern apparatus for oil lamp, the principal feature of which is the rapidity with which it may be unpacked and fixed in position, and a slide projected on the screen. On this occasion the operation lasted about five minutes. For reasons connected with the patenting of the lantern, we were asked to withhold any description of it.

Mr. W. G. Blackie, of the Blackfriars Sensitising Company, exhibited and explained the Anschütz Instantaneous Hand Camera.

Mr. H. B. Sharp, of Messrs. Sharp & Watmough, Liverpool, exhibited and described the "Aptus" Universal Camera. [See page 348.]

Votes of thanks to Mr. Stuart and the other gentlemen concluded the proceedings.

LONDON AND PROVINCIAL PHOTOGRAPHIC ASSOCIATION.

May 19.—Mr. G. W. Austin in the chair.

Mr. R. R. Beard was elected a member.

Hand Cameras up to Date.

Mr. H. B. Sharp (of Messrs. Sharp & Hitchmough, Liverpool) exhibited and explained the "Aptus" Universal Hand Camera, which is capable of being employed either as a hand or stand camera at will. Mr. B. Foulks-Winks showed Messrs. Adams & Co.'s "Adams" Hand Camera, their new "Ideal," and the "Pocket" Hand Camera. The latter folds into a very small compass and has a swing back. Mr. J. A. Sinclair exhibited the "Hat" Camera of Messrs. Adams, which can be fitted to an ordinary felt hat.

A question from the box asked whether aluminium fittings to cameras would stand the effects of sea moisture. Mr. A. Mackie saw no reason why they should not, and also thought that aluminium could be lacquered as well as brass.

"How to Ascertain when the Fixation of a Silver Print is Complete."

The Hon. Secretary read Mr. Lyonel Clark's reply to the letter which he had written to that gentlemen, asking for information on this question. [See p. 343.]

Mr. Mackie said Mr. Lyonel Clark had not answered the question; he had not told them how to ascertain when the fixation was complete. This was an example of the careless way in which some examiners put questions. Mr. Clark did not seem to realise that they had asked him to answer his own question. How did he expect the candidates at the City and Guilds examination to answer a question which he (the examiner) himself could not answer?

Mr. P. Everett pointed out that Mr. Clark may have asked the question, well knowing that there was no answer to it and in order to ascertain the amount of knowledge among the students.

Mr. W. E. Debenham said that that would be a very unfair thing of a teacher, and he did not believe Mr. Clark would do that. The questions put should be such as to elicit the information the student had obtained from his own work under the teacher. He (Mr. Debenham) did not think the question was a catch. It was a thing which, in the present state of our knowledge, could not be known.

Mr. A. Cowan thought it was not fair to run down Mr. Clark, who had given them a fair answer. Mr. Clark did not know whether he had tried the bichromate test.

Mr. T. Bolas said bichromate had an effect on silver nitrate and not on the chloride, and therefore the examiner could scarcely have considered the question.

Mr. Everett said it was not an infrequent thing for mathematical questions that were incapable of solution to be asked.

Mr. Cowan hoped that the meeting would thank Mr. Clark for his communication although the question had not been satisfactorily answered.

Mr. A. Haddon concurred, and also suggested that Mr. Clark be asked what answer he would give full marks for if he set the question. Mr. Haddon said he should be glad to receive information on the point.

The thanks of the meeting were formally voted to Mr. Clark, and it was also decided to ask him for an answer to Mr. Haddon's question.

The remainder of the evening was passed in a lantern display, Messrs. W. P. Dando, G. W. Austin, S. J. Beckett, W. Bouts, J. S. Teape, and W. H. Harrison exhibiting slides. The latter gentleman showed a slide of Mr. Maskell's cat, photographed, presumably, by means of a flashlight. The facial expression of the animal created much amusement.

North London Photographic Society.—May 17, Mr. J. Douglas in the chair.—The evening was announced as a Technical Evening, and was commenced by the Fry Manufacturing Company showing the different forms of the "Griffiths" hand camera, which caused much interest. The principal subject for the evening was *Films*, and specimens were shown of the well-known Fry films. Messrs. Edwards had sent some samples of their films, and Mr. J. D. England also sent some specimens of film negatives and film carriers. The SECRETARY, in giving his experience of film working, stated that it had been practically confined to England's and Edwards' films, of both of which he spoke in high terms, showing negatives taken by himself which fully bore out his opinion. Up to half-plate there was no difficulty in using ordinary dark slides provided the thickness of the glass was made up for by a piece of dark cardboard. A film carrier made by the Secretary for hand-camera work was shown, and the various advantages of films were fully discussed. Next meeting, June 7, *Retouching*, by Mr. Redmond Barrett.

North Middlesex Photographic Society.—May 23, Mr. C. O. Gregory in the chair.—Mr. MUMMERY read a paper on *Gelatino-Chloride-of-silver Paper* [see page 346], showing examples on various brands of paper toned by different formulæ. He then gave a demonstration of the process, and answered questions on technical points. Competitions of views at the last three field days were then held. Votes of merit were awarded as follows:—"Edgware," Mr. S. E. Wall; "Chigwell," the Secretary; and "Chingford," Mr. S. Barnard. The winning prints will be exhibited on the walls of the meeting room for a few weeks, and finally preserved in the Society's album. A number of the first two issues of *Photographic Work* were distributed among the members. The next meeting will be held on Monday, June 13, when Mr. F. E. Jones will demonstrate the Plantinotype Company's new cold-bath process. Visitors welcome.

People's Palace Photographic Club.—May 20, Mr. C. W. Gamble (Vice-President) in the chair.—Question: Is a coloured stain on a negative proof that the plate is old? In reply: If, with normal development a stain in the form of iridescence appears round the edge of the plate, it may be taken that the plate is old, but a stain sometimes occurs with a comparatively new plate after very prolonged development. Work was shown by Messrs. Marriott, Walker, Cable, and Patten. Subject for the evening, *Developing Snap-shot Exposures*, which elicited a discussion. Mr. G. Patten was strongly in favour of dry pyro with ammonia, which he found gave an excellent printing negative, even if developed somewhat thin. For bare or under-exposures his formula would be half to one grain pyro, quarter of a grain bromide, six minims ·880 ammonia. This would be modified for different makes of plates. He found Paget 50 plates would stand forcing with a very large percentage of ammonia. Mr. T. LAWDAY said more detail could be obtained from under-exposures by giving the plate a bath of ammonia before developing. He preferred dry pyro for this class of work. Mr. R. BECKETT thought the next best developer to dry pyro and ammonia was a mixture of eikonogen and hydroquinone, which was extremely useful for a plate that could not be developed with ammonia. It was quick in its action. Mr. R. H. EDWARDS had lately used a mixture of rodinal and hydroquinone with good results. The rodinal, he said, had the effect of "flashing up" the image, and the hydroquinone gave density.

Kensington and Bayswater Photographic Society.—May 23, Mr. H. G. Hannaford in the chair.—Mr. G. BURSNELL read a paper and gave a demonstration on *Bromide Enlarging*. Mr. Bursnell showed how bromide enlarging may be done by either day or artificial light. In referring to the different developers he believed that the most satisfactory results were obtained by taking the developer recommended by the makers of the paper used. He made some satisfactory enlargements on the new rapid paper manufactured by the Eastman Company. Mr. Bursnell stated that where formerly he gave an exposure of one hour with this paper he now gave a few minutes only; this, of course, with a comparatively poor light. He recommended in all cases to make trial exposures, as there are so many factors which govern this important part of the work, the chief of these being the actinic power of light, the density of the negative, the presence or absence of stains, and the ratio of the stop.

Putney Photographic Society.—May 17, Annual General Meeting, Dr. W. J. Sheppard in the chair.—A satisfactory report was read and adopted. The HON. SECRETARY expressed his regret that he would be unable to continue the secretaryship, as he was leaving the neighbourhood. The following officers were then elected:—*President:* The Hon. Baron Pollock.—*Vice-Presidents:* Rev. L. Macdona and Dr. W. J. Sheppard.—*Council:* Dr. J. F. Farrar, Messrs. H. Faulkner, T. Gilbert, Chas. Ballard.—*Treasurer:* Mr. Wm. Martin, jun., 4, Lower Parkfields.—*Joint Hon. Secretaries:* Messrs. L. S. Zachariasen, Alfred Villa, Putney Bridge-road, and W. F. Gorin, 3, Montserrat-road.

South London Photographic Society.—May 16, the President (Mr. F. W. Edwards) in the chair. Mr. W. I. Chadwick, of Manchester, delivered a lecture on *Stereoscopic Photography*. The lecturer said the first thing to be understood was the reason why it was necessary to have two pictures to prevent complications and difficulties arising. He proceeded to explain this by remarks on monocular and binocular vision, illustrated by diagrams of the human eye on the blackboard, referring particularly to the difficulties of a person with one eye in judging the distance of various objects. A man with one eye could only do so by size, and it could easily be shown that in many instances his judgment could not be relied upon. A man with two eyes did not judge distance by size alone, but, by reason of the convergence of his eyes, saw objects solid, or, in other words, in relief. If two pictures were produced such as would be seen by each eye, and were viewed at the same angle, the objects depicted would be seen of the natural size, and with the same amount of relief. He then showed the diagram of a box which he had made some years ago, by which pictures taken with lenses of different foci appeared of the same size, and the person who viewed them would be unable to tell which picture was taken with the longer or shorter focus lens. After explaining the principle of the stereoscope, he showed the apparatus, which he used to produce negatives and transparencies. In making negatives it was necessary to have two lenses of equal focal length, and mounted on the lens board three inches apart. In making prints from the negatives the centres of the pictures were reduced to two and a half or two and five-eighths inches apart, a distance equal to that which the eyes are apart. The positions of the two pictures were also reversed after printing, the right-hand picture placed where the left was and the left-hand picture where the right was. When the various operations were successfully performed, and the two pictures viewed in the stereoscope, the objects depicted appeared as in nature, each standing out in advance of the others in their proper position. After an address of about one hour's duration a series of questions from an appreciative audience were asked, and lucidly and humorously answered by the lecturer.

Brixton and Clapham Camera Club.—May 17, Dr. Reynolds (President) in the chair.—Dr. T. CHARTERS WHITE gave a paper upon *Photo-micrography*. The lecturer said that the subject which he had chosen was a vast one, on account of the great strides made in photography during the last twenty years as applied to scientific research, inasmuch as photographs may be taken of an eclipse of the sun, of the entire heavens, or even of the smallest bacillus. In the first place, in carrying out his directions, no large outlay is required for apparatus, and any person who has a camera and a microscope can produce excellent results. Dr. White said he usually used an oblong lidless box placed on its side, the microscope and lamp is then placed inside this box, and a black curtain is pulled over its front, and shuts in the light, so that all operations could be performed in the same room. The box is firmly screwed on to a stout base-board, the middle length of which slides in and out by being dovetailed on the outer sides. At its distal extremity an ordinary printing frame is screwed as a carrier to hold the focussing screen and eventually the plate. These several parts must be accurately squared with the box and optical plane of the microscope, or the image will appear blurred. At the end of the box, next the carrier, an aperture is made to allow of the insertion of the microscope tube. The lamp is then lighted, and the object placed upon the stage of the microscope, and the image projected on to a glass plate in the carrier, which glass plate may have clean white paper upon it, and, the velvet carrier being pulled down, a brilliant image is thrown upon the focussing screen, and that part of the subject selected that it is desired to photograph, and thus roughly focussed. If a picture suitable for a lantern slide is required, the sliding base with its carrier is pushed closer to the box; and, if a more extensive amplification is wanted, the sliding base is drawn out. On removing the paper screen and inserting a piece of plate glass ruled in squares with a diamond, with the ruled glass next the microscope, the image may be viewed with an ordinary focussing glass by resting it against the glass plate and by bringing the aerial image of the object into exact focus with the fine lines, which would approximately occupy the plane of the gelatine emulsion on the sensitive plate. If the above details have been properly attended to, there is no reason why the photograph should not be absolutely sharp. The lecturer advised the following as approximate exposures:—When using 1½ objective, 3·45 seconds; ⅔ objective, 7·90 seconds; ⅓ objective, ½ 3 minutes; ¼ objective, 2·7 minutes; ⅛ objective, 4·10 minutes. Any developer which will give good contrasts is suitable. At the conclusion of the paper, an excellent set of microscopic slides were shown, which fully bore out all that Dr. White had said in his paper. A hearty vote of thanks was passed to him for his eminently instructive lecture.

Birmingham Photographic Society.—May 24.—The first whole-day excursion of the season was made to Buildwas Abbey and Much Wenlock Priory. Twenty-three members joined the excursion, under the leadership of Mr. William Jones; and 180 plates were exposed, chiefly whole-plate and larger. For the comfort of the party, a saloon was provided by the early express, and a delightful day was spent amongst the grand rivers of these exceptionally interesting places. For the information of photographers unacquainted with these historical ecclesiastical remains, it may be stated that Buildwas presents unique examples of the transition period from Late Norman to Early English. The extensive ruins of Wenlock Priory comprise beautiful examples both of Norman and Early English work of what was once the most important monastic establishment of the Midlands, and which are now carefully preserved by their present owner. An excellent luncheon was provided by Mrs. Butcher, of the "Raven Hotel," to which justice was done."

Tyneside Camera Club.—May 21.—There was a club outing to Marsden Rock and the coast. There was an excellent attendance of ladies and gentlemen. Plates were exposed on the famous Marsden Rock, Bottle Rocks, and numerous others. There was a strong west wind, which *was* a nuisance, and sundry sharp showers, which brought the waterproof focussing cloths into frequent use; notwithstanding the weather, a very pleasant day was spent.

Edinburgh Photographic Society.—The second of the members' Saturday afternoon rambles, which had been arranged for June 4, as stated in our report, page 318, has been altered as to date, all the other details remaining as stated. The date is now to be Saturday, May 28, at 2.10, Waverley Station.

Edinburgh University Photographic Club.—May 16, Dr. Drinkwater in the chair.—The first and principal business of the evening was the reading a paper and exposition on *Exposure Meters and Tables* by Mr. F. Dundas Todd, in which he set forth the factors determining exposure, such as the quality and state of the light for interior and exterior views, the lens, its focus and aperture, the plates in use, &c., and explained his comparative experiments with the various commercial "aids to timing exposure" in the market, describing the principle on which each of them was contrived. In the course of discussion which ensued, several of the members stated that they possessed exposure meters, but each of them admitted that they never used them save for the purpose of recording the exposure, as they had either found or believed the figures of the tables untrustworthy. Of the named meters three of the members had Watkins', and Mr. PEARCE stated that so far as he had used it with a single dozen of plates the results were fairly satisfactory, but he found his difficulty to be in deciding what subject number to take. Dr. PATERSON stated that he had now so accustomed himself to the use of a meter that he felt it would hardly be worth his while trying to photograph without it. Before using the meter he used to get about one good plate in a dozen, but now, with its use, they were nearly all good. Mr. HARRISON said that since he had become accustomed to the use of his meter he never had a wrongly exposed plate. Mr. TODD related a peculiar experience to him in platinum printing. For several days in the previous week he had been printing a set of platinum

prints, and, as a rule, had only two or three indifferently exposed, but one day, when the sky was quite clear, and a keen biting east wind was blowing, he had difficulty in deciding when the printing was complete, although he had taken the same care as on previous days, the result being that the batch of prints made on that day were practically worthless, all of them being under-printed. The CHAIRMAN (Dr. Drinkwater) said he was so sensible of the effect of this phenomenon that he always doubled his exposures during an east wind, and advised his audience to follow his example, which was that of the older photographers of the pre-gelatine period, the truth of it having even passed into a rhyming proverb. The Mr. F. Dundas Todd here mentioned has just been awarded one of the five out of twelve gold medals given at the present Boston, New York, and Philadelphia Photographic Exhibition, which have been adjudged to British subjects. His pictures were *The Smiddy*, exhibited at the Edinburgh Society's members' exposition, and *Baiting the Lines*. He is the only Scotchman among the five medal-getters, and this is the second gold medal for his works which he has obtained during the last few weeks.

Correspondence.

☞ *Correspondents should never write on both sides of the paper.*

DEPTH OF FOCUS.

To the EDITOR.

SIR,—The discussion of yesterday evening at the Photographic Society of Great Britain has led me to believe that Mr. Debenham and myself could not agree in questions relating to photographic optics. I therefore consider that it would be unnecessary for me to "furnish two diagrams of lenses of the same focus" for his special consideration. This, after all, would perhaps not be admitted to elucidate the subject, which can best be decided by the usual optical tests, which are the most accurate and certain. The taking of pictures is seldom resorted to, and then only to show a practical effect.

I have referred to the pinhole stop as a fundamental example of infinite depth of focus. A photographer may try to take a landscape view with a perfect lens with large aperture, and fail for want of this depth of focus; this he at once obtains by the adaptation of a small stop.

If Mr. Debenham is prepared to discuss the subject of depth of focus, and the question of oblique pencils in photographic lenses, I refer him to the recent work of Dr. Schroeder, which is the only one that treats thoroughly of the optics of the subject. I am aware that he has access to the work. He will find the matter fully dealt with at pp. 148–152.—I am, yours, &c., F. H. WENHAM.

May 25, 1892.

PHOTOGRAPHY IN THE COLOURS OF NATURE.

To the EDITOR.

SIR,—From the reply of Mr. Ives (p. 333) to my letter (p. 318) I learn that Mr. Ives continues to make erroneous statements in order to defend the original errors which I have contradicted.

Mr. Ives asserts that the Franklin Institute gave me a *full hearing* before deciding the question of originality of orthochromatic photography in favour of him.

I reply that I have never received any official letter from the Franklin Institute in those terms. I only got from Professor Himes, of Philadelphia, a very friendly private letter, asking for several dates and details of my invention, which, in Himes' own words, "is only second to Daguerre's."

But it seems that Mr. Ives himself does not trust the verdict of the Franklin Institute, for several years afterwards he recognised the invention of orthochromatic photography as mine in your JOURNAL, 1891, p. 101.

In reply to Mr. Ives' assertion that "after Mr. Bothamley's translation I gave *five* as the minimum number of negatives and prints" I use, I request Mr. Ives to read my original paper of 1885 (mentioned on p. 318 of this JOURNAL), wherein I said not a word about "five negatives as a minimum."

The method of working with three negatives, claimed by Mr. Ives, is an old one, tried before mine by Cros, Ducos du Hauron, and Albert.

If Mr. Ives says "nothing was heard about his (my) trying to do it with three negatives until after I (Ives) proved," &c., I reply that, after Ducos du Hauron's publication (printed *twelve* years before Ives'), everybody could make coloured prints, with so-called complementary colours, without waiting for Ives' paper; even more, as in Ives' patent for 1890 not a word is said about coloured *prints*, but only about coloured lantern pictures, whilst in the same year I already exhibited *prints* in natural colours, worked out after my principle, which were exhibited in Berlin.

I agree with the *Standard* of May 10, "that the pictures are not colour-photographs in the popular sense of the term, but rather a combination of chromo-photography with optical illusion; and such is never likely, in its present state at least, to advance beyond the state of being a pretty experiment."

With regard to the so-called "complementary colours," I have developed my opinions over doubtfulness not only in my book on *Colour-sensitive Photography*, 1885, p. 137, but also in two lectures before the Society of Berlin Physicists (President, Helmholtz), *vide* report of the mentioned Society, April 20, 1888, and January 10, 1890, and I show it every year by experiments in my lectures on *The Theory of Colours* at the Royal Technical High School, Berlin. Perhaps Professor S. Thompson had never read those papers. DR. H. W. VOGEL.

Berlin, May 21, 1892.

STAINS ON PRINTING-OUT PAPER.

To the EDITOR.

SIR,—May we be allowed to explain one or two points in your correspondent's letter, which may otherwise be misleading?

1. We did not advise more gold than that on formula; we wrote that the gold in Mr. Meigh's bath was evidently almost exhausted, as proved by slowness of toning.

2. The pieces of paper were not signed, but only initialled, and it was impossible for us to decipher the initials and trace from whom they came until we saw Mr. Meigh's letter in your columns.

3. The pieces of paper referred to have been sent to Mr. Meigh to-day. They were printed and toned the day they reached us, and are perfectly free from markings.

4. We therefore adhere to our statement, that the markings are due to the cause we suggested.

We apologise to Mr. Meigh for the accidental separation of his letter and the pieces of unprinted paper, and feel sure he will allow us to make this public statement of the position of affairs.—We are, yours, &c.,

THE BRITANNIA WORKS CO., LIMITED.

Ilford, London, May 20th, 1892.

RECRYSTALLISED SILVER NITRATE AND "COSMOS."

To the EDITOR.

SIR,—I would suggest that the increased sensitiveness of bromo-iodide gelatine emulsion, made with fused nitrate of silver, as noted by Mr. Barker, is due to the fact of the fused nitrate being alkaline, and containing a small proportion of nitrite of silver. The accelerating powers of the nitrites were pointed out as far back as 1855 by the Abbé Laborde and Mr. Hadow nearly simultaneously.

Those of your readers who do not know the difference between ordinary nitrate of silver and the recrystallised salt will find it explained in the fifth, and probably later editions, of Hardwich's *Photographic Chemistry*. The recrystallised is not so attractive in appearance as the ordinary salt, being in less transparent crystals, probably from being dried by heat, but, which is the matter of importance, is free from organic impurities and from acidity; and, as old collodion workers know, it made a much more satisfactory bath. During thirty years' experience as a photographic chemist, I sold many thousand ounces of both kinds, and believe that the books of the chief refiners would show that the genuine recrystallised article was largely used during the last fifteen to twenty years of collodion being in vogue. I think that "Cosmos" is mistaken in supposing that many dealers acted as dishonestly as his sharp-practising principals.—I am, yours, &c., HENRY WHITFIELD.

May 23, 1892.

PHOTOGRAPHIC PRINTERS.

To the EDITOR.

SIR,—As an old reader of your valuable JOURNAL, I take the liberty of addressing a few lines to you. I am a photographic printer with about twenty years' experience, and about five months ago I had the misfortune to be thrown out of employment, through no fault of my own; and ever since I have been advertising and answering advertisements in the columns of your JOURNAL, and, up to now, have not been successful in obtaining a situation to suit me. I obtained one, but was only there a short time, as the gentleman said I was too old, and that he wanted a young man. I might mention that my age is thirty-nine. Surely a man is not too old at that age?

Now, what I should like to ask you, Mr. Editor, is whether photography is in such a bad state that a respectable man cannot get a situation, or is the market overstocked with printers, or is there any other means of obtaining a situation otherwise than through the columns of your JOURNAL. I never had such a difficulty a few years back, say, ten or twelve years back. For the last nine years I have been employed by one firm as carbon printer, so you may judge by that I have a good character. I have been asking 30*s.* for carbon, and 25*s.* a week for silver printing; is that a reasonable salary?—I am, yours, &c., UNFORTUNATE.

[Thirty-nine is by no means an age at which a man might be considered as too old for a photographic printer, or, indeed, for any other ordinary occupation. The wages our correspondent asks are extremely reasonable, but photographic printing has of late been reduced to such a degree of ease and simplicity that we fear the market is overrun with printers—good, bad, and indifferent.—ED.]

Answers to Correspondents.

All matters for the text portion of this JOURNAL, *including queries for "Answers" and "Exchanges," must be addressed to* "THE EDITOR," *2, York-street, Covent Garden, London. Inattention to this ensures delay. No notice taken of communications unless name and address of writer are given.*

**** Communications relating to Advertisements and general business affairs must be addressed to* "HENRY GREENWOOD & Co.," *2, York-street, Covent Garden, London.*

F. E. S. B.—Castile soap may be dissolved in plain alcohol.

E. SCAMELL.—In America the slides are placed "landscape way."

P. M.—If the bitumen will not dissolve in turpentine, it is useless for photographic purposes.

S. O. L. D.—Your letter cannot be inserted unless with your full name and address appended.

D. MACBETH asks for the address where he can obtain some of Monckhoven's pigmented (gelatine) tissues or films.—We believe such are not now obtainable commercially.

S. W. E.—For a small camera canvas cases are quite equal to leather, while they are both lighter and cheaper. For larger sizes leather cases are to be preferred, as they offer a better protection to their contents.

APPRENTICE.—For ordinary purposes, for testing the strength of the sensitising bath for paper, the argentometer is sufficiently accurate in practice. For theoretical accuracy the volumetric method must be employed.

N. SMITH is learning photography, and, having a good deal of spare time, wishes to learn lantern-slide making and colouring, and would like to know of a work on the subject.—Do any of our readers know of such a work?

A. HORTON.—We cannot discover the maker of the lens from the monogram, which is apparently that of some firm for whom it has been made. If we can get it interpreted we will intimate the same through this column.

R. A. C.—You are under a misapprehension. The original South London Photographic Society, like the North London Photographic Association, ceased to exist many years ago. Societies under the same or similar names are quite new ones.

WARDEN.—You cannot possibly prevent a photographer from taking views of the outside of the church from any point he chooses, provided he is not trespassing on your private property. You, the rector, or even the bishop himself, have no copyright in the building.

A. L. (Bedford).—If the stock solution of pyrogallic acid becomes slightly discoloured when first mixed and yet works well after several weeks keeping there is not much the matter with it. Don't trouble yourself about a trifling discolouration so long as the solution works all right.

C. A. GILES writes to know how to make a good varnish that will not stick when the negative is printed in the sun.—If our correspondent will refer to the ALMANAC for the current and past years, he will find several formulæ, which include the best that have been published.

Z. Y. X. (Leeds).—The cause of the starch not sticking must be that it is not properly made. Probably it is too thin; make it as thick as possible. Then, when it is cold, beat it up with a spoon, and apply it either with a tolerably stiff brush or a sponge. The latter is preferable for large sizes.

N. M. L.—Hunt's works are now all out of print—so also is Bigelow's *Album*—and have been for many years. The former may sometimes be met with at second-hand bookstalls. But your best way of obtaining copies of any of these works is to advertise your requirements in the columns devoted to advertising purposes.

H. WHITEFORD.—An ordinary Albion printing press will do quite well for collotype printing. Indeed, this form of press is still used by some of the best workers. In your initial experiments we should not advise you to go to the expense of a regular collotype press, as you already possess one that will answer every purpose.

A. TILLEY.—It is quite a mistake to surmise that, because a camera is very light, as well as portable, it will not be steady when set up in the field. But it must be kept in mind that this most essential quality—rigidity—can only be obtained by good workmanship and with good material, things that cannot be expected in low-priced apparatus.

EXPOSURE says: "Will you inform me the principle of Watkins' Exposure Meter, and the working of same, and how the correct exposure is obtained for various subjects, and stops used?"—Such information is, we believe, sent out with each exposure meter, but probably the makers will be happy to supply you with a pamphlet on the subject.

COPYRIGHT asks: "Who has the legal right to the copyright in a group in which there is a large number of figures? Can I copy and reproduce any single figure in the said group, and can the relatives of that person (deceased) restrain me from selling a copy or exhibiting it?"—Perhaps some legal reader can supply an answer to our correspondent's questions.

BLACKENING ZINC.—A correspondent, whose name we have lost, recently inquired concerning the blackening of zinc. We have since then obtained the following information. To stain zinc black, immerse in a solution of nitrate of iron, five drachms to the pint of water; or in a solution of protochloride of tin, one drachm to one pint. The zinc must previously have been made quite clean.

L. S. D. says he has a quantity of old frames of what is known as German gold, which have become almost black. He wishes to know if they can be regilt.—These frames, if they be, as we surmise, of the usual German moulding, are simply covered with silver foil and lacquered; then the most economical way of dealing with them is to use them for lighting the fire with, and getting new frames made, utilising the old glasses and backboards.

T. MOLLOY.—If the emulsion, the formula for which you obtained from the 1885 ALMANAC, does not give you sufficient sensitiveness, increase the time of cooking, say, fifty per cent., or even a hundred per cent. if necessary. Fog is the only limit to the time of cooking with a good emulsion.

FERROUS says: "Can you kindly inform me what is the most suitable paper for giving black lines on white ground? I have a formula that gives very good lines, but cannot get the white ground all over; have tried numerous samples—albumenised gave the best, but in this case the albumen dissolved in sensitising, and gave a smeared ground."—If our correspondent desires to have prints from line negatives, and these are dense and clear enough, the simplest plan would be for him to use either bromide or platinotype paper.

H. W. B.—The interposition of a plate of even optically worked glass will alter a focus made previous to such interposition. Hence it will be advisable to focus after the screen is inserted. Try this experiment: Take a small telescope and focus sharply an outside object through a plate-glass pane. Then raise the window, and it will be found that the object is now less sharp, and requires refocussing. Something analogous to this occurs with the microscope as regards the adjustment for the covering glass of the object.

DAGUERREOTYPE says: "I should esteem it a favour if you would inform me the best treatment for a Daguerreotype which a customer of mine removed from its frame and proceeded to dust with a handkerchief, with the apparent result of removing portions of the image. The surface was not tarnished, but simply dusty, and the amount of friction applied was very slight."—We fear there is no practicable way of restoring the spoilt image. For the best method of copying and reproducing it, see leading article in the JOURNAL a few weeks ago.

A. H. asks: "Which is the best style and colour of blinds for the roof and side of a studio? Should any of the glass be obscured or frosted? Would six feet be high enough at the side with an angle of sixty degrees for roof? Is "Darlot" a good lens maker? My studio is twenty feet long; would any whole-plate lens take a full-length cabinet in it?"—1. Dark blue spring blinds. 2. If there are buildings in the vicinity which would obstruct the light, frost the sides of the studio to a height of about seven feet. 3. Yes. 4. Yes, providing the lens is of not too great a length of focus.

MR. J. BUNCLE, of Edinburgh, sends us his catalogue. This is largely devoted to detailed particulars of many well-known types of cameras and other articles.

WEST LONDON PHOTOGRAPHIC SOCIETY.—May 28, Hampstead Heath, 3.30. Cycling division meet at headquarters 2.45, or "Askew Arms," Uxbridge-road, 3 p.m.

MR. W. F. STANLEY'S catalogue includes particulars of a large and varied collection of photographic apparatus, &c., for which there is a constant call among amateurs.

WE have received the catalogue of Mr. R. C. Murray, which contains particulars of photographic apparatus and materials, selected with Mr. Murray's well-known care and judgment.

PHOTOGRAPHIC CLUB.—June 1, *Photo-micrography*, Mr. T. Charters White. 8, *Dodging Negatives for Printing*. Outing, next Saturday, May 28, Merstham. Train from Cannon-street seventeen minutes past two.

LONDON AND PROVINCIAL PHOTOGRAPHIC ASSOCIATION.—June 2, *The Telephotographic Lens*, Mr. T. R. Dallmeyer. 9, Members Open Night. 16, *Photogravure*, lecture by Mr. Howard Farmer. Visitors are welcome.

WE learn that rodinal, the new developing solution, with the powers of which we ourselves recently expressed ourselves pleased, is being largely used by many professional photographers. Messrs. R. W. Greeff & Co., the agents, have recently acquired the wholesale agency for Dr. Andresen's paramidophenol and eikonogen as well as of Dr. Byk's products.

FROM the catalogue of the Fry Manufacturing Company we learn of the approaching issue by this firm of a brand of plates specially designed to resist halation and give great latitude in exposure. Reductions are announced in the prices of Fry's bromide opals and celluloid films. The catalogue, which is a complete and comprehensive guide to the firm's specialities, has several specimen illustrations on papers of its own manufacture.

MESSRS. ADAMS & CO. write to solicit our help in trying to trace a thief or thieves who seem very successful in purloining lenses from them. They have, of late, missed quite a number, but unfortunately have no clue whereby to trace same. A few days back, however, a Wray lens, five-inch rapid rectilinear, with Waterhouse stops, was taken, and this lens bears the number of 4968. Messrs. Adams will reward any one giving information leading to the detection of the thief.

JOURNAL OF PHOTOGRAPHY.

No. 1674. Vol. XXXIX.—JUNE 3, 1892.

PHOTOGRAPHIC PRINTERS.

The letter of a correspondent in our last issue, complaining of his inability to procure employment as a photographic printer, notwithstanding his possession of considerable practical experience, and, doubtless, the necessary qualifications added to most moderate expectations as to wages, has brought us one or two rejoinders, which appear to us to reflect with tolerable accuracy the views of those who are in a position to judge of the reasons why so many find this branch of photography unremunerative and otherwise unsatisfactory. Briefly expressed, the implication is that really good photographic printers are scarce, which, considered in conjunction with what we said last week as to the simplicity of making photographic prints nowadays being responsible for the dissemination of a great deal of mediocrity and sheer inability among photographic printers, undoubtedly conveys a good idea of the exact position of matters.

While pointing out, however, the simplicity and ease of modern photographic printing, we, of course, should not be understood to allege that the qualities in a man necessary for the production of good and uniform impressions from most kinds of negatives with which he has to deal are one whit less needful than in former times, or that, in fact, the inherent difficulties and peculiarities of each process have been any more than partially removed by recent improvements and advances. But, compared with negative-making, the production of paper positives of a sort, without regard to professional requirements, demands such small skill, that we can hardly be surprised that so many persons should seize upon photographic printing as an easy means of gaining a livelihood, with, as a rule, disastrous results to themselves, and, as we have already said, the effect of swelling the ranks of photographic printers with incompetents and duffers.

Would-be photographic printers are constantly submitting specimens of their work to us with a request for our opinion of it, coupled with what we should consider a fair salary to ask. In most cases these aspirants begin photography as amateurs, and, failing in their own employment, decide with a light heart to engage in photography professionally. Now and then, to be sure, a few really good prints—carefully printed from properly exposed, developed, and retouched negatives, and, so far as the particular specimens go, uniformly toned—are shown us, but such cases are quite the exception. Usually the specimens are from indifferent negatives, and of poor quality throughout, besides failing in the chief essentials of uniformity of depth and tone. Such people are too often persuaded of their own cleverness that it is a matter of difficulty to convince or prove to them that their work falls below professional standard, and a little advice to acquire greater proficiency does not always encounter a proper reception.

But, in addition to this class, unskilful printers are common enough in the ranks of those who have acted professionally as such for years. The fact is, a good printer is the product of a deal of practical study of the different branches of his subject. He must be a sound judge of the capacities, peculiarities, defects, and good points of each of the innumerable negatives that passes through his hands, which alone, from his standpoint at any rate, is equivalent to a small education in itself. He must be able to suit the process to the negative or the negative to the process at call; he should have the ability to convert faulty negatives into good printing ones. Each of the printed-out or developed methods (for example) of printing in platinum, carbon—silver in albumen, collodion, gelatine; of plain paper printing, with all the details and distinctive peculiarities and points of each process should be literally at his finger ends. The printing-in of clouds, masking, vignetting, combination printing, are also all necessary adjuncts which, in addition to an ability to produce good and uniform prints, and a complete acquaintance with the principle and practice of development, toning, fixing, and washing, all go to make up a good printer. We fear, however, that such a range of knowledge is not very prevalent among individuals, and that, indeed, the number of those who may fitly claim a perfect command over at least one process from beginning to end is not great.

When we come to reflect on the many qualifications which are demanded of a photographic printer—all of which we have by no means enumerated—there is no room for surprise that capable men are not so easily procured as professional photographers could desire. The more we ponder on the matter, and the more experience we have of it, the greater is our conviction that good printers are scarce, and, when obtainable, are assured of fair and adequate remuneration. And what, after all, is the cause of this scarcity? What, again, is the reason for the existence of such a very low average of skill and knowledge among the rank and file of photographic printers? The answer, we believe, rests on two facts. First, the growth and multiplication of new processes; and, second, the disinclination or neglect of young printers to make themselves thoroughly acquainted with the principles and practice of each of those processes as it is introduced. In most cases they are content with merely superficial knowledge, which, when put into practice, lands them into all sorts of difficulties, to the disgust of their employers and the degradation of their work. Study and practice, the experience to be gained from occasional failures, an unwearied application to even the minutest details are necessary to ensure successful printing from the negative. How often do we find these qualities, singly or in combination, in a photographic printer?

It is singular that at a time when, as we have often pointed out of late, printing processes are being very much improved and simplified, a decline in the skill of printers should be

remarked. Is photographic printing now so easy that printers should fall into the error of supposing that individual or specialistic ability is no longer necessary? Are all our modern negatives so good that particular treatment or attention to them is superfluous? Do not printing processes still require as hitherto to be minutely understood, and closely studied? We submit these questions with the conviction that, if they are answerable in any other manner than that which we suppose feasible, an additional clue will be found for the explanation of the falling average of ability among photographic printers of which complaint is made. In former times, when the number of printing processes in vogue was limited, photographic printing, judging by the numerous examples which have happily survived, was as a rule more carefully executed than now. Will the same be said of modern printing a few years hence?

DO NEGATIVES FADE?

With regard to this question we have recently been, by the kindness of a professional photographer, put in a position to make a thorough examination. "What man has done man can do" is a proverb which has not a universal application in our science, at least not in the way that it might be popularly expected to have. The conditions governing the production of certain results are too often so completely unknown that their reproduction is entirely fortuitous. But, when in one person's hands they are repeated indefinitely, it may be assumed that these may do what man has done; and, in the case in point, we will proceed to describe the latter.

We were allowed to examine negatives counted by the tens of thousands; they were on dry plates by almost every known maker, and let us state at the outset the result was thoroughly reassuring, so much so, as to enable us to give an emphatic negative to the question which forms the title of this article. We do not for one moment wish our readers to think that we have examined all these plates; that would be absurd. But it may be as well, *en passant*, to make a small calculation bearing on the matter. Suppose even twelve thousand negatives were examined, and only ten seconds given to each, the examination would last for four days of nine hours each, the work being done without cessation! What we have done is to dip here and there, beginning at the first dry-plate negative taken, and at intervals, without selection, take a negative and thoroughly inspect it. The result was that we did not meet with one single faded negative. But the owner of the plates informed us that there were a few damaged plates, and we inspected them closely. The result was that they might be placed in two classes—evidently imperfectly washed plates, and those where mercury had been used as an intensifier, there being finally a small residuum of unexplained causes. It was not the case that all the mercurially intensified films had proved unstable. Some were perfect though many years old, while others had turned into that "sere and yellow leaf" so familiar to those with long experience in this kind of intensification.

Lest the question of manner of storage may be supposed to affect the result, we may say that the particular examples we examined were stored in two entirely different modes, yet the result was the same—practically, complete exemption from any injury. Some were packed in the boxes originally used for holding the unused plates as issued by the maker, a piece of paper being placed between each to avoid scratches. Others were merely placed in racks upon shelves open to all atmospheric influences.

One point, however, deserves noting: every plate was varnished. Our photographic friend was most emphatic upon the desirability of this being done, that he said he would never think of printing from a negative of any value which had not first been varnished. In proof of the need for this, he selected for us, knowing where to find them easily, some beautiful plates quite ruined by stains. These, as he explained, were clearly the result of silver. One print had been taken from them before varnishing, and it was occasionally found that, whether through imperfect drying of the paper (very improbable) or from the frames or pads being damp, or perhaps the last trace of hygroscopic moisture not expelled from the film, a portion of the silver had set off from the paper on to the film, and gradually made its presence evident by a brown stain, increasing in intensity daily while printing was proceeding, till at last the plate became useless for good prints. We dwell fully upon this cause, as it is one that may probably be acting in a large number of cases throughout the country at the present time.

A further explanation was offered us as to the injury visible upon other negatives shown us. They were of larger size, and we were told that frequently it had happened that they had been washed under the tap by placing them on a levelling stand, and allowing the water to run on them for an hour or so. Most of the plates were washed in a tank with grooved supports, the water continually running in and out for about two hours, when the washing was considered complete, which, indeed, was proved in the results shown. It is an old story how difficult it is to wash out the soluble contents of the film, even with so porous a texture as wet collodion; far more so is it when a comparatively impermeable film like gelatine is employed. If any one will watch the effect of a stream of running water upon a film containing a coloured liquid, the experiment will be instructive, and show how curiously the liquid seems to cling to and remain upon the surface, though the flush of water be considerable.

We may conclude our remarks by quoting another proverb, "One swallow does not make a summer;" but the result of our examination, as explained, has been to prove that, if gelatine negatives be well washed, dried, and varnished, they may be considered as imperishable as, if not more than, collodion negatives; and the test of time has proved the latter to be completely stable.

New Gold Compounds.—M. P. Mercier recently read before the Photographic Club de Paris a brief paper setting forth a method of obtaining a number of new neutral salts of gold for employment in the toning bath. On account of this neutrality baths made with such compounds are said to have most excellent keeping properties. The compounds prepared by M. Mercier consist of auro-phosphates, auro-acetates, auro-succinates, &c., which are formed by neutralising gold chloride with an alkaline phosphate or acetate, as the case may be, in a small quantity of water, and crystallising the salt by evaporation. The only compound so prepared commercially as yet is the auro-phosphate of soda, which, by simple dissolution in water, yields a ready-made toning bath, which is said to give rich violet-black tones, either with albumen or emulsion papers.

Fluoréal.—The same gentleman (M. Mercier) has also incurred the serious responsibility of bringing out a new developer, which, however, appears to have some novel properties. It is called Fluoréal, the base being presumably para-amidophenol. The solution is coloured by the addition of fluorescein, which is said to prevent veiling of the plate during development.

Anhydrous Sulphite of Soda.—With fluoréal M. Mercier employs caustic lithea in conjunction with anhydrous sulphite of soda. The advantages of the anhydrous over the ordinary salt as a preservative are said to be that, thanks to its pulverulent form, it dissolves quickly; that, being free of any water of crystallisation, one part by weight is approximately equal to two of the ordinary salt; that it does not oxidise, and is therefore, unlike the common sulphite, not liable to conversion into sulphate, which is generally supposed to exercise a restraining action in development. M. Mercier states that he has exposed anhydrous sulphite of soda to the air for several months, and in analysis it only exhibited very faint traces of sulphate. The same gentleman speaks highly of caustic lithia as the alkali in preference to potash or soda hydrates.

Meteorological Photography.—In reference to Mr. Clayden's brief lecture on this subject the other night (see page 364), it may be useful to point out that the British Association some time ago appointed a Committee, consisting of Messrs. G. J. Symons, F.R.S. (Chairman); R. Meldola, F.R.S.; John Hopkinson, F.L.S., F.G.S.; and Arthur W. Clayden, M.A., F.G.S., F.C.S. (Secretary), to take the matter in hand. Photographs are desired of clouds, lightning, hoar-frost, remarkable hailstones, snow-wreaths, avalanches, glaciers, storm-waves, water-spouts, tornadoes, dust-whirls, halos, parhelia, or any other meteorological phenomena or their consequences. Prints, which may be mounted or unmounted, should be sent to Mr. Clayden, at Warleigh, Tulse Hill Park, London, S.W., who also supplies a leaflet giving brief instructions for taking cloud and lightning photographs, which all interested in the subject should possess.

Retouching.—Of the numerous subjects of interest (and otherwise) which are being constantly brought before photographic societies, that of retouching probably receives the smallest attention. This, perhaps, arises from two causes, which we may indicate as, severally, the paucity of individuals competent to discourse upon retouching, as well as to practise it; and the circumstance that amateur retouchers are few and far between, and that, therefore, the available number of persons willing, if able, to treat of it before a Society is small. So many amateurs nowadays attempt portraiture, that to them the opportunity of acquiring a knowledge, however limited, of how to improve their portrait negatives must be welcome. Such an opportunity will be given to the members of the North London Photographic Society on Tuesday night next, June 7, when Mr. Redmond Barrett is to introduce the subject of retouching, and will, we believe, accompany his discourse with several practical demonstrations of the use of the pencil. Mr. Barrett's mastery of his subject will surely attract a good attendance of members and visitors.

American Photographers in London.—During the past week we have been favoured with calls from quite a number of American photographers now in this country, foremost of whom is Miss Catherine Weed Barnes, of the *American Amateur Photographer*. Miss Barnes, as our readers are aware, is to attend the Convention and read a paper, and in addition hopes, during her stay, to visit many of the picturesque parts of the country with the camera. Mr. J. Carbutt, of Philadelphia, also called upon us the other day, and showed us the new "Genie" hand camera, a very clever little instrument, together with some remarkably fine prints from panoramic negatives, 18 × 48, taken on his films, as well as several smaller prints, 18 × 20, from negatives on his orthochromatic films. Señor Ferreira, of Rio Grande, a well-known Brazilian amateur, also waited upon us. Mr. F. E. Ives, of Philadelphia, whose paper on *Heliochromy* we reproduce elsewhere, informs us that he will not be able to attend the Convention. We believe he goes immediately to Switzerland, and thence back to America.

Mr. Lyonel Clark and the London and Provincial Photographic Association.—Elsewhere we print a letter from Mr. Lyonel Clark, pointing out that, when he was asked by the members of the London and Provincial Association to answer a question as to the method for ascertaining when the fixation of a silver print is complete, he was unaware that the question was addressed to him in the capacity of Examiner of the City and Guilds Institute. Mr. Clark was not the examiner on that occasion, and consequently did not set the question of the very existence of which he was ignorant. We are certain that the somewhat sharp and hasty criticisms which some of the members of the London and Provincial Photographic Association passed upon his communication will be regretted by nobody more than those gentlemen themselves. Mr. Clark is known to have given much attention to the theory and practice of silver printing, and to us, and possibly to him, it appears only natural that his views, on a point of importance arising therefrom, should be sought. It is unfortunate that an erroneous assumption should have been the means of crediting him with the authorship of the question which has given rise to misunderstanding on both sides, and we think that Mr. Clark should be the recipient of an explanation from the Association. Knowing the admirable manner in which the affairs of that body are administered by its excellent Secretary, Mr. Drage, we have no doubt that this has been done.

JOTTINGS.

A YOUTHFUL monthly contemporary having been asked by a correspondent to say what it thinks of the various photographic publications, falls into the old, old blunder of placing the BRITISH second to another weekly journal on the score of age. For his information, and that of others who may be lured into a similar mistake by the magnetic attraction of imitation, I beg to state that THE BRITISH JOURNAL OF PHOTOGRAPHY dates its birth from the year 1854, whereas the *other* only saw the light in September, 1858. True, its original title has been modified, and from a monthly it became in succession a fortnightly and a weekly, but these are no reasons why it should be persistently deprived of its claim to seniority. A man who changes his name and "keeps up" his birthday twice a year instead of once does not reckon his age from the date of those changes, but from the date of his birth. By the way, your juvenile contemporary dubs you the "watch dog!" The attributes most desirable in a watch dog are fidelity and reliability, so the compliment is a pretty one. But, when he goes on to satirise you for demolishing the numerous re-inventions which are constantly popping up in the photographic world to-day, he omits to acknowledge what I am sure everybody of proper feeling must own, and that is, that "THE BRITISH" renders an incalculable service to the photographic community in preventing those same re-inventions from being palmed off as new and original. If there were no BRITISH JOURNAL OF PHOTOGRAPHY just now, it would be necessary to invent one.

I am much obliged to Mr. Frederick Park, Mr. W. Cooper Edmonds, and "Old Silver Bath" for their comments on my last "Jottings." I agree with the first-named gentleman that *f*-32 is *practically* the same in all lenses, *i.e.*, 1/32 of their equivalent foci; but, as the foci of lenses employed for a quarter-plate, or indeed any other kind of work, are not constants, and cannot be guessed, "*f*-32" without the stated focus is only a piece of relative and not precise information. The point, however, is a very trifling one. As to density, with a rapid rectilinear lens and a large stop, being greater in the centre of a picture than at the sides, owing to the oblique rays being reduced in area by the lens mount, who thinks of employing the full aperture of a rectilinear lens for making negatives for enlarging?

"Old Silver Bath's" optimism is of that cheery order which entices its possessor into the habit of shutting one's eyes to facts. It is not only because I assisted my employers in cheating the public (I hope "Old Silver Bath" does not, after all, live in a glass house) that I hinted that recrystallised silver nitrate and the ordinary silver nitrate were often held by the vendors to be synonymous terms, but because I used to find that the average photographer was incapable of appreciating the difference between the two salts that, despite "Old Silver Bath's" chivalrous defence of "other and respectable dealers and makers of photographic chemicals," I must still stick to my original thesis. Assuming "Old Silver Bath" to be a genuine and not a

spurious veteran, I wonder how much nitrate of potash he has bought at the price of silver nitrate in his time? To say that he has "strong evidence" to the effect that a bath made with the recrystallised silver nitrate would keep in good working condition longer than one made with the commercial salt is a piece of intelligence only to be paralleled by the news that Holland has fallen into the hands of the Dutch.

Perhaps it is because I never attend the meetings of any of the Photographic Societies that a great deal of what I read as taking place at them only appeals to my sense of the ludicrous, and makes me wonder if those who speak thereat divest themselves of their common sense with their hats and overcoats. Here, for example, is Mr. Haddon, at a meeting of the London and Provincial Photographic Association, reported (I hope incorrectly) to recommend amateurs to go in for collodion positive work instead of gelatine negatives, in order, I suppose, to benefit—or, rather, not to injure—the professional. As well advise all city men to walk instead of riding to business, so that the boot and shoe industry might not become extinct. I should like to have a photograph of the high-souled new-style amateur in course of putting the Haddonian precept into practice; so, no doubt, would guileless Mr. Haddon. Assuredly the millennium would then be at hand.

If individual amateurs, or amateurs as a body, are ever desirous of lending a helping hand to the rank and file of professionals, who are undoubtedly the greatest sufferers through the vulgarisation of photography, it seems to me that they might easily do so by making a rule of not giving their friends prints of the portraits they may take of them, or of the views of their houses, and so forth. Let them make their friends a present of the negatives or duplicates of them, and tell them to take these to the professional to be printed. Thus the profession and the trade generally will be assisted, the friend would not miss the few pence charged for the prints, and the amateur will not only have spared himself the humiliation of having to give more or less bad prints, but will have the pleasure of knowing that, after all, he is a friend and not an enemy of the professional. Did not the late Mr. William Adcock, as large-hearted a man as you could find, once publish a similar suggestion in your pages?

I have said I never go to any of the Society's meetings. Though once an *habitué* of several, I placed myself on the permanent absentee list several years ago, because, being one who never took part in the discussions, it became, after a time, too great a strain upon my charity and endurance to sit under the deliverances of the same handful of clever persons week after week, and month after month, and to acquiesce in, by my silence, the severe snubbing which was regularly dealt out to younger, and therefore less informed, members who were guilty of the presumption of not always saying ditto to their seniors. Were I still a society man, nothing would so quickly convert me into a photographic Narcissus than the incident which occurred at the meeting where Mr. Haddon delivered himself of his remedy for languishing professionalism. The examiner at the last City and Guilds Institute is said to have asked the following question of his students, "How can you ascertain when the fixation of a silver print is complete?" What the answers given were I have no means of telling; but the question, somewhat unwarrantably, I think, is brought up to the meeting of a Society which has no connexion with the examiner or the examination, and the wise members thereof, being unable to answer, decided to ask the examiner to do so. Nobody has any right to assume that the examiner's question was not put in good faith, possibly in order to probe the ideas of the students on the point, and therefore the action of the London and Provincial Association in catechising him strikes me as uncalled for and undignified. Surely the members ought to know that catch questions are among the few means an examiner has at hand of flooring his mortal enemy, the crammer.

So, Mr. G. H. Slight thinks that any one having the photograph of a dead friend that had faded since his death might half naturally ascribe it (the fading since death) to some sort of sympathy with the death of the individual rather than to chemical changes. I can corroborate Mr. Slight's fellow-passenger in his discovery. I have noticed the photographs of dead people fade more rapidly than they did when the originals were living, chemical changes playing no part in the accelerated fugacity. But I have also occasionally noticed the same phenomenon occur with the photographs of living people, but not so often as with those that had died. The photographs were generally in albums, and the fading was due to the circumstance that they were frequently examined by sympathetic surviving relatives or friends in the best light available. "Proof of the correctness" of such changes is easily obtained, Mr. Slight. COSMOS.

THE CAMERA AND THE CONVENTION: OR PICTURESQUE SCOTLAND AND PHOTOGRAPHY.

V.

STRONACHLACHER is the name of the landing-place at the west end of Loch Katrine. We believe there has been a new hotel built at this spot since we were there. It is here that the Glasgow Corporation "put up" when on their waterworks inspection, the aqueduct by which the water of Loch Katrine is conveyed to Glasgow beginning near this place.

Down both sides of the loch from this upper reach many fine effects are to be procured, but by no means possessing charms equal to the Trossachs end of the lake.

INVERSNAID.

From this point the coach starts for Inversnaid, across Glen Arklet, a distance of four or five miles. This road is so hilly and hard upon the horses that it may be walked almost as quickly as driven. We have successfully walked the distance against the coach. Starting your walk immediately after leaving the steamer gives you the advantage over the coach by the time it takes to load and get away.

Inversnaid, that we now reach, is a boating station near the head of Loch Lomond. There is a good hotel here, and close by the side of it is a fine waterfall that descends from the promontory above into the loch. This waterfall is on the River Arklet, and certainly has been photographed many thousand times—it is so handy and so picturesque.

The late Mr. Ralston used to tell a good story about an old Highlander that he once met at these falls. Having got into conversation with him, Mr. Ralston offered the Gael a drop out of his flask, when the old Highland man, in a serious tone, remarked, "This is gran' water, sir. This water stands any quantity o' *whuskey*, sir."

Which he proved on the spot by returning the flask empty.

In the glen over the falls a good general view of Loch Lomond may be obtained.

Above Inversnaid, about a mile, is Rob Roy's Cave, and further on you reach the pier where you disembark for Inveranon Hotel.

BALLOCH.

Loch Lomond is too expansive for general views, and we have also found working from the Balloch end more convenient and more profuse in subject, using a small boat and going short distances, and the steamer when distances are beyond the reach of a small boat. The road up what is called the side of the Loch from Balloch is very disappointing, as the estates and private properties lie between the road and the Loch, and for miles, sometimes, you do not get near the water.

On one occasion we took the boat to Luss, with intent to walk to Balloch by road, which we had never done before. This was a distance of eight miles, and we fully expected to get any quantity of pictures by the way, and it really was very annoying, two-thirds of the way being between stone walls and such like, and the open parts of no moment. That day we met a photographic enthusiast on his bicycle, who had exposed his twelve plates on a flock of sheep, and was done with photography for the day.

Balloch is situated just where Loch Lomond runs into the Leven. At this place boats can be had at any time, and from the mouth of the river to either side of the Loch is but a short row, and as you creep along the shores the picturesque can be easily seen and noted, and landing at any desired place is in most cases easy. When staying here, we used to get many pictures that way, and found it both easy and enjoyable.

WATER EXCURSIONS.

These small boat excursions embrace the grounds of Balloch Castle, and on as far as Inch Murrin on the right, while on the left hand are

Cameron House, Auchendennan, Auchinheglish, and Arden, all estates quite near, and all worthy a visit.

Then come the trips by steamers. Luss is the first village on the way up the loch, and it is well situated for some good work, but the stopping places all the way up will repay the trouble of going to them.

Rowardennan is specially interesting. This is the starting-place for those intending to "do" Ben Lomond.

At the Glasgow Convention there was one trip on this loch which will be remembered with pleasure by many. It was under the leadership of Mr. John Stuart, the journey being up the loch to Tarbet, and across the hill to Arrochar on the Clyde.

From Balloch some enjoyable little trips can be had, notable amongst these are the grounds of Tillichewan, Mount Misery, Glen Finnich, a short glen but deep, precipitous and grand. And on the line to Glasgow, Dumbarton Castle.

Glasgow.

Then come we to Glasgow, the second city of the empire, which already has had its "innings" in the way of entertaining the Convention gathering, but probably a day will be given to the city of the west, as was done to our Edinburgh friends when the meeting was in Glasgow.

Glasgow, like all other commercial cities, looks, on the face of it, as if there was not much to photograph, but amidst all the hurry and bustle of a toiling, crowded city there is always something to be found and noted worthy of the picture taker.

The Cathedral stands first in point of importance and interest. The exterior possesses many points of pictorial interest which must be familiar to many whilst the interior of the church, with its Lady's Chapel and crypt, and stained-glass windows, supply material for a large series of pictures that would delight the heart of those who enjoy this class of work, and many enthusiasts take a great pleasure in it.

Next is the Necropolis, rising immediately behind the Cathedral. It is very imposing. It rises some three hundred feet, showing terrace on terrace cut out of the rocky hill, with monuments and trees and shrubs all blended in one harmonious whole, rendering the cemetery a striking picture of peace in the midst of its busy surroundings. The parks are of some photographic interest, especially the West End Park. It is unfortunate that at present one-half of it is torn up in the constructing of a district railway; but, still, down by the Kelvin it is fairly free from the obstruction, and on the other side of the river, where the Exhibition stood, the park will be found in very good condition, and it is along the banks of the Kelvin on this side that the best pictures of the University are to be got, with good reflection effects in the water and picturesque groupings of foliage. The Queen's Park, usually called the South Side Park, is close to the historical ground where the battle of Langside was fought, and many points of beauty are to be caught in this park and its surroundings.

East End Park.

The Alexandra, or East End Park, is not in a favourable position for picture taking, being in the immediate vicinity of iron works and other smoke-producing manufactories, which tend to keep it in a perpetual atmosphere of haze—besides, the park is still too young for the obtaining of good general effects. The quay on the river down by the Broomielaw, where the crowds of boats and people are coming and going all day long, will commend itself to many. The number of instantaneous pictures that have been taken here, both artistic and interesting, argues that such scenes of bustling life have a charm for many photographers. Busy streets and handsome buildings are to be found everywhere in this city of the West; but architectural street subjects are rather at a discount by our Convention friends unless they embrace old churches or monuments that possess an interest or story of their own—these also are to be found in Glasgow—but for the most part, in the tide of time, they have got crowded out of sight away in old streets and back ways, and, midst the constant hurry of a commercial life, get dropped out of memory and neglected.

As a centre for the photographer, Glasgow stands unrivalled for surroundings possessing beauties that appeal to every taste, whether river, or lake, or mountain, or flood. For a little outing there is Campsie Glen; not much of it, but what there is is very charming. Then, for a day, there is Hamilton Palace and Bothwell Castle. We believe that special permission must be had to get into Hamilton Palace and grounds, but they are well worth some little trouble in obtaining this. The ruins of Bothwell Castle are romantically situated close to the river Clyde, its ruined walls decorated by Nature with wild flowers and trailing plants. The surroundings are well suited for pleasing work, without much trouble in obtaining points of view, the Clyde here being very picturesque.

COMPOSITE HELIOCHROMY.

[Journal of the Society of Arts]

Most people look to original discovery for the solution of photographic problems, and most photographical problems are solved by original discovery. There have been a few important exceptions to the rule. The production of the so-called half-tone photographic block—the latest substitute for wood-engraving, now grown to a very important industry—is one example. The first practical solution of this problem—a process which I patented in America in 1881—was a purely mechanical invention utilising photographic processes already known. The so-called Woodbury-type process is another purely mechanical invention, based upon well-known photographic processes.

Collen's Process.

The method of colour photography, which I have named composite heliochromy, and which the French prefer to call photochromy or composite photochromy, is also an invention utilising comparatively old and well-known photographic processes. It is not a simple invention, but comprises several inventions by different men. The original suggestion was made twenty-seven years ago by Her Majesty the Queen's painting master, Henry Collen.* Briefly stated, Collen's idea was to make three negatives of an object, one by red light, one by yellow, one by blue—the so-called primary colours of Brewster—to print from each pair of these negatives (superposed as one) a transparent positive having the colour (in the shadows) of the light that produced the third negative, and to superpose these coloured positives on a white surface. A Baron Ransonnet, of Austria, is credited with the same suggestion in the same year, but I have not the reference.

It was not possible to carry out Collen's suggestion at that time because there was no known process by which photographic plates could be made sensitive to the separate single colours only; and no photographic plates were sensitive enough to red and yellow to admit of the production of such negatives by exposure through selective colour screens. Had it been possible to carry it out, the results must have been very imperfect, not only because the entire procedure is based upon a false and misleading theory of colour, but also because superposing two negatives to act as one would double the intensity of such parts as represented white, grey, or pale-coloured objects, with the result that, if the colour prints were made to show all the details of the negatives, the finished heliochromes would show all bright colours as if mixed with equal parts of black pigment.

Ducos Duhauron's Patent.

On November 23, 1868, Ducos Duhauron, of Paris, applied for a patent† for a process which differed from Collen's only in the manner of carrying out the same idea. Like Collen, he assumed that the spectrum is made up of three primary colour rays and mixtures thereof. He said, "My procedure rests on the principle that the simple colours are limited to three—the red, the yellow, and the blue—the combination of which, in divers proportions, produces the infinite variety of shades in nature." Like Collen, he expected to solve the problem by superposing red, yellow, and blue prints from negatives made by yellow and blue, red and blue, and yellow and red light. But, instead of using plates sensitive to simple colours only, he proposed to use plates sensitive to all colours, and to prevent the action of colour rays not wanted by filtering them out with coloured glasses placed in front of the sensitive plates; and, instead of superposing two negatives to act as one to make a colour print from, he proposed to make two colours (that is, two-thirds of the spectrum) act to produce each negative, which amounts to the same thing. He proposed to make one negative through an "orange" screen, calculated to absorb the blue light and transmit the red and yellow; one through a "violet" screen, calculated to absorb the yellow light and transmit the red and blue; one through a "green" screen, calculated to absorb the red light and transmit the yellow and blue.

It was no more possible to carry out this idea in Duhauron's way in 1868 than to carry it out in Collen's way in 1865, although Duhauron, having succeeded in making photographs by exposing ordinary photographic sensitive plates through glasses that were orange, green, and violet to the eye, imagined that he had succeeded in carrying it out. In reality, the photograph made through an "orange" screen must have been made chiefly by either the green, the yellow-green, or the ultra-violet spectrum rays, as can readily be proved by photographing the spectrum itself through a bright orange screen (not an orange-red one), on such a plate as he used. The photograph made through a "green" screen, the transmitted freely both the yellow and the blue rays, must have been made chiefly by the blue rays, and the photograph made through a

* The British Journal of Photography, October 27, 1865, p. 547.
† Class xviii., sec. 3, serial No. 83,061.

"violet" screen must have been made without any action by the red rays and with a great deal by the invisible ultra-violet rays.

Charles Cros' Modification.

Soon after Duhauron published the details of his process, Charles Cros, of Paris, published another modification of Collen's idea.* Like Collen, Cros proposed to make one negative by the action of red light, one by yellow, and one by blue; but by exposing the sensitive plates through red, yellow, and blue glasses, instead of employing plates sensitive to the single colours only. Instead of superposing the respective pairs of these negatives to make each colour print, he proposed to make a green print from the negative made by red light, a violet print from the negative made by yellow light, and an orange print from the negative made by blue light. Cros's plan was free from the defect of doubling intensity on those parts of the negatives representing pale or uncoloured objects; but the advantage gained in this way would be lost again in the production of green, violet, and orange-coloured prints.

The principle of colour selection advocated by Duhauron is identical with that distinctly proposed by Collen, to whom alone the credit of the original invention appears to belong; but Duhauron and Cros, besides proposing a more reasonable plan for obtaining the negatives, further suggested that optical superposition of positive images from the three negatives might be substituted for the superposition of transparent coloured prints.

On December 3, 1869, M. Poirée, of Paris, in a communication to the Photographic Society of France,† suggested that better results might be had by making a greater number of negatives—a separate negative for each spectrum region.

Dyed Silver Bromide.

In 1873 Dr. H. W. Vogel, of Berlin, discovered that bromide of silver can be made sensitive to the less refrangible spectrum rays by treatment with certain dyes; and this, with the subsequent discovery of other and better colour sensitisers, supplied the means for carrying out either Collen's or Poirée's idea. Duhauron, one of the first to avail himself of these discoveries, made some practical progress, and, in 1876, abandoned Brewster's colour theory, and patented a modified process,‡ based upon the observation that, while there appeared to be "seven" principal spectrum colours, three colouring substances would "serve to express them." The colouring substances he named for this purpose are blue, carmine, and yellow; and he decided that, in order to make such a process reproduce the colours of nature, the negatives should still be made through orange, green, and violet glasses.

Chlorophyl and Eosine Plates.

At this period Duhauron's orange-screen negatives were made on chlorophyl plates, and must have been made chiefly by the red spectrum rays. In 1878,§ he announced that he had substituted eosine for chlorophyl, so that he must finally have made them chiefly by the greenish yellow spectrum rays. The significance of this fact has not been generally recognised. The production of three negatives, one through an "orange screen, one through a "green" screen, and one through a "violet" screen, is a very indefinite procedure. A negative may be made through an "orange" screen chiefly by the action of red rays, or orange rays, or yellow rays, or yellow-green rays, or green rays, or ultra violet rays, according to the character and intensity of the "orange" colour of the screen and the method of sensitising the photographic plate for colour. Duhauron, who never recognised the necessity of testing his process by photographing the spectrum itself, not only did not find out what it is necessary to do in order accurately to reproduce the natural colours, but at different times he did very different and inconsistent things without himself knowing that he did so. The facts can very readily be demonstrated by first showing the spectrum absorption of various "orange," "green," and "violet" screens, and then photographs of the spectrum which have been made on plates differently sensitised for colour. I shall now proceed to demonstrate this point.

In 1879, Cros‖ also abandoned the idea that red, yellow, and blue are primary spectrum colours, but held that there are three primary spectrum colours and mixtures thereof, and that these primary colours are orange, green, and violet. Like Duhauron, he decided to make negatives through orange, green, and violet screens, and prints in blue, carmine, and yellow. Cros, like Duhauron, was apparently ignorant of the fact that very different negatives can be produced through one and the same screen, and he also allowed all of the invisible ultra-violet rays to act in producing the negative of the "violet" screen.

In 1885, Dr. H. W. Vogel* proposed to make the colour prints with dyes identical in spectrum absorption with the colour sensitisers employed in making the negatives. This does not amount to a principle of colour selection, because the entire spectrum can be photographed on plates sensitised with dyes that cannot be combined to reproduce some colours, and even without any dyes at all, by the use of suitable colour screens.

The Young-Helmholz Theory.

Some time previous to 1889, I do not know the exact date, the Young-Helmholz theory of colour vision was first recognised in connexion with this subject by Dr. F. Stolze, of Berlin.† He said, "Although the colours correspond with certain external processes in nature, there is also no doubt that colour as such is nothing objective, but a subjective sensation, based upon the peculiar irritation of the visual nerves by those external proceedings. We can, therefore, only hope to produce a picture in natural colours when we are enabled to reproduce upon the same the proceedings which furnish to us the colour impression." "Thomas Young . . . . assumes that there are three kinds of nerve fibres, sensible to red, green, and violet. Objective homogeneous light excites all three; but with red the first is excited strongly, the second and third weakly; with blue, the second and third moderately strong, the first weakly; with violet, finally, the third strongly, and the first and second weakly. If all three kinds of nerves are equally strongly excited, the impression of white light will take place." Dr. Stolze suggested, but rather indefinitely, a procedure which, although not really representing the application of this theory, was more nearly consistent with it than were any of the older ones. The theory itself was defective as a basis of procedure, Clerk Maxwell having shown that the fundamental red sensation is not at all excited by the blue-green, blue, and violet rays, the fundamental green sensation not at all by the red or violet rays, and the violet sensation not at all by the red, orange, or yellow rays.

Mr. Ives' Improvements.

It was at this stage that, after ten years of experiment along the same lines as Duhauron, Cros, and Stolze, I myself made certain improvements, and claimed the credit of bringing order out of chaos by devising a procedure which not only recognises the facts which support the modern colour theory, but which definitely represents the application of that theory.

This process, although in a general way somewhat similar to those which preceded it, really represents a distinctly new principle, which is that of making three photographs by the action of light rays as they excite the three fundamental colour sensations, and superposing these photographs by means of lights or in transparent pigments which suitably represent the corresponding fundamental colour sensations.

In February, 1888, I demonstrated, at the Franklin Institute, Philadelphia,‡ a process in which the colour selection was according to a definite plan, and proved by photographing the spectrum itself, adjusting the colour screens to obtain definite density curves in the spectrum negative. This was the first publication in which a really definite mode of procedure was indicated; but it was not until November of the same year§ that I demonstrated the method so modified as to definitely represent the application of the Young-Helmholtz colour theory, in accordance with Maxwell's measurements of the relative power of different spectrum rays to excite the respective fundamental colour sensations.

Maxwell's Diagram.

A little study of Maxwell's diagram, showing the result of his measurements, will show that the application of this new principle involves very important departures from the older methods of procedure. In this diagram, which I reproduce, 1, 2, 3 are spectrum colours which represent fundamental colour sensations, because each excites one sensation only, and *a*, *b*, c are curves showing the relative power of different spectrum rays to excite the respective fundamental colour sensations.

The first remarkable fact to be gathered from the study of this diagram is, that the rays which represent a fundamental colour sensation are in no case the ones that most powerfully excite that sensation. The red sensation is excited by all the spectrum rays from red to green, but most powerfully by the orange; and the negative to represent the effect upon the fundamental red sensation must therefore be made, not through a red glass, or by the red rays, but by the joint action (in definite pro-

* Described in *Photographic News*, October 8, 1869, p. 483.

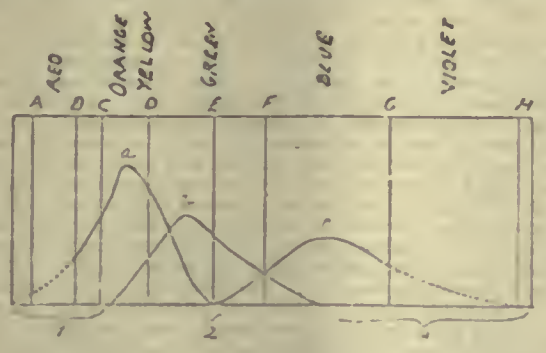
§ *Ibid.*, Jan., 1889.

portions) of the red, orange, yellow, and yellow-green spectrum rays. The negative to represent the effect upon the green sensation must be made by the joint action of the orange, yellow, yellow-green, green, and green-blue spectrum rays, in proportion to their power to excite that sen-



sation. The negative to represent the effect upon the blue-violet sensation must be made by the joint action of the blue-green, blue, and violet spectrum rays, in proportion to their power to excite that sensation.

By photometric measurement of the density curve of a spectrum negative, the relative amount of action by the different spectrum rays may be found. It is, therefore, only necessary, in order to secure action by different rays in any definite proportions, to use such a combination of sensitive plate and colour screen as will yield a spectrum negative having a density curve corresponding to the graphic curve representing such proportionate action.

Sensitive Plates and Colour Screens.

Sensitive plates and colour screens that will yield three negative of the spectrum, having intensity curves like the three graphic curves in Maxwell's diagram, will produce a permanent photographic record of the effect of light from any object upon the three fundamental colour sensations. This can most readily be accomplished (with separate plates) by exposing a cyanine-stained rapid gelatine-bromide plate through a double screen of aniline yellow and chrysoidine orange, of suitable intensity, for the red sensation; a commercial "orthochromatic" plate through a screen of "brilliant" (aniline) yellow, of suitable intensity, for the green sensation; and an ordinary gelatine-bromide plate through a very thin piece of plane polished green glass for the blue-violet sensation. The screens that will secure the same results all on one kind of plate are far more complicated and difficult of adjustment; but any one who possesses a photospectrograph and a good assortment of coal-tar dies, can, by the exercise of some skill and ingenuity, make the adjustments for himself.

The set of three photographs of any object made as I have indicated of course show no colour whatever, but they contain in a permanent form such a graphic record of the natural colours that, in order to reproduce them to the eye, it is only necessary to superpose the three positive images either upon a screen or upon the retina of the eye—the one representing the red sensation with pure red light, the one representing the green sensation with pure green light, and the one representing the blue-violet sensation with blue-violet light. The blending of the three images will excite exactly the same sensation as the light coming directly to the eye from the object itself. The synthesis can also be made with superposed transparent colour prints, and this is the plan which has received the most attention, although the simplicity of *optical* superposition commends it to scientists, and is really more convincing to everybody.

Optical Superposition.

Both Duhauron and Cros had the idea of synthesis by optical superposition as well as by colour prints, but neither of them succeeded in carrying out the idea practically. Superposition by triple optical lantern projection was first carried out successfully by me in my demonstration at the Franklin Institute, Philadelphia, in February, 1888, showing a landscape photograph from nature. I employed a single lantern box, having three optical systems close together, with a triple limelight jet, and the three positives mounted side by side in a single wooden frame behind red, green, and blue glasses. A considerable variety of subjects were shown with the same lantern in November of the same year, when I first clearly stated and demonstrated the principle which represents the application of the Young-Helmholtz-Maxwell colour theory.

The first workable plan of optical superposition other than by lantern projection was devised by Antoine Hippolyte Cros, brother of Charles Cros, and patented in 1887. In this device, the three pictures are arranged relatively to each other like the steps of a staircase, and by means of a peculiar system of mirrors, some of which are attached to the face of a rapidly revolving wheel, with open spaces between them, the different pictures are seen by the eye in one optical plane, in such rapid succession, that they appear like a single picture with colours blended. The same device, which is a very ingenious one, was to be used also for making the negatives, but it is so clumsy, so troublesome, by reason of the necessity for providing means to keep the mirrors in motion, and includes such an extremely narrow angle of view, that I believe it has no practical value.

Both Duhauron and Cros taught that synthesis by optical superposition should be accomplished with the same mixtures of light rays that acted to produce the different negatives. The picture made through an orange screen was to be seen by the light transmitted by the same, or an exactly similar screen, and so on.

I hope I have made it clear that such a procedure is quite irrational, in view of the facts which support the Young-Helmholtz-Maxwell colour theory. The photograph made by the joint action of various different colours of spectrum rays must be seen by rays of one colour only. Spectrum rays of various colours excite one fundamental sensation, but only spectrum rays of one single colour will serve to represent that fundamental sensation.

I have taken particular pains to emphasise this fact in every paper I have published upon this subject, but have not yet succeeded in impressing it upon the minds of the French writers, who continue to assert that my procedure does not differ in any essential particular from that indicated by Duhauron and Cros. I think that this one difference alone is of vital importance.

Experiments in the Triple Lantern.

The application of the Young-Helmholtz-Maxwell theory involves important changes from the older methods, not only in the negative process, and in the synthesis by optical superposition, but also in the production of permanent colour prints. Theoretical considerations alone led me to conclude that a transparent colour print from either negative could be made to perform exactly the same function that the positive transparency from the same negative performs in the synthesis of triple-lantern projection, and a simple experiment with the triple lantern confirms my conclusions.

The white disc that we obtain in screen projection by mixing the red, green, and blue-violet lights, corresponds to the white paper which may form the basis of a permanent colour-print heliochrome. When we insert the positive of the red sensation in its place in the lantern, its shadows cut off the red light, leaving the disc still white, except in the shadows, where there remains only a mixture of the other two lights, green and blue-violet; a transparent print from the same negative performs the same function when laid upon the white paper, provided that its shadows also cut off the rays that excite the fundamental red sensation, but freely transmit the green and blue-violet. I have found that a coal-tar dye, sold as "thio blue A," absorbs those rays which excite the fundamental red sensation, but freely transmits the green and blue-violet; a Woodbury-type process print in this colour fulfils the requirement for a permanent print to represent (by transparency) the effect upon the fundamental red sensation. By a similar process I have found that fuchsine fulfils the requirement for making a print to represent the green sensation, and aniline yellow the print for the blue-violet sensation. It is true, as I have already pointed out, that these permanent colour-print heliochromes will show a slight degradation of colour in ordinary white light, but they should exactly reproduce the natural colours when viewed in a white light produced by mixing the red, green, and blue-violet spectrum rays.

The theoretical conditions of success have, therefore, been realised for the negative process, and for all three methods of synthesis.

The Heliochromoscope.

But there is another aspect of this subject, which, from a practical and commercial point of view, is quite as important as that of realising the theoretical conditions of success. I am of the opinion that, however perfect results this process could be made to give, it would not be reasonable to expect it to be commercially successful, so long as complicated by the necessity for making three separate photographic negatives and three separate photographic colour prints, in order to obtain a single reproduction in colours. Such a complicated procedure might be carried out successfully by experts, dealing with such subjects

as paintings or similar art objects, but would not be available for landscape photography, or in the hands of amateurs.

The only way to make the process simple and reliable enough to be available generally is to reduce the number of negatives to one, and dispense with the colour-print process altogether. This I have accomplished by the invention of a camera that makes the three pictures on a single plate, by one exposure from one point of view, and a device, which I have named the heliochromoscope, that optically recombines the triple black and white photograph into a single photograph reproducing the natural colours. With this camera (about the size of a kodak) and the heliochromoscope (the size of a hand stereoscope), the reproduction of the natural colour by photography is not only made practically available, but reduced to the simplicity of stereoscopic photography.

I wonder if people are prepared to realise the full significance of this fact. The hope of producing colour *prints* by a direct process is calculated to discredit the value of an equally simple method that accomplishes substantially the same result in a different way. I said "substantially the same result;" but, in a way, it is a better result, because it is quite impossible that any coloured picture, with its distracting surroundings and surface reflections, should ever produce such a perfect illusion of nature itself as we may obtain with this little instrument, consisting of several small mirrors, two of them transparent, placed at certain angles with reference to the photograph, and enclosed in a box. If the heliochromoscope was merely a box for seeing photographs in colours, it might be regarded with indifference; but I hold that it is as far from being merely that as the phonograph is from being merely a device for making a noise by turning a handle. It capable of accomplishing for us, in the reproduction of colours, more than the phonograph accomplishes for us in the production of sounds, because the illusion is more perfect. I quite believe that the writer who, in a recent article in *The Speaker*, described the heliochromoscope as a toy, comparable to the kaleidoscope, would have been capable, under similar circumstances, of comparing the phonograph to a baby's tin rattle.

Simplifying the Colour-Print Process.

I have also tried to simplify and perfect the colour-print process. The employment of the new triple camera, making one operation take the place of three, is one step in that direction. The use of the dyes I have mentioned, corresponding to the colours produced in screen demonstration, is another. The production of a single print instead of three, cutting the images apart only when ready to be dyed, is another. Experiment with the Woodburytype process is another. The Woodburytype process offers the vitally important advantage for reproduction in large numbers that, having found experimentally the right amount of dye required in each of the three colour prints, an indefinite number can be made without any variation; it will be available for the commercial production of lantern slides. These appear to be real advances; but, after all, the further complication and mechanical difficulties of carrying out the print-making process render it comparatively unsatisfactory up to the present time, and the value of composite heliochromy must be estimated, for the present, on the basis of its application to the photographic reproduction of the natural colours by optical superposition.

If the heliochromoscope is the only solution of the problem that is sufficiently simple to be practicable for general introduction, there is, nevertheless, a field for the application of the method of colour projection for lecture illustration. Here, also, we escape the complication and mechanical difficulties of colour printing, and obtain results which are permanent, as far as the colour record goes, and which can be shown to many people at one time. It will be necessary, however, to employ the arc electric light, in order to project landscape views at night as perfectly as they have already been projected by sunlight. The value of the method cannot be fully demonstrated with the limelight.

In conclusion, I would like to say another word to emphasise the fact, which I think is quite sufficiently demonstrated in the heliochromoscope, that, although we are not able to make photographs in natural colours of exactly the kind that people have been looking for, we have, nevertheless, found a true solution of the problem of reproducing the natural colours by photography, as remarkable in its results as the telephone or phonograph, more perfect in the illusion of nature than would be possible in coloured pictures, and almost as easy to realise as stereoscopic photography. It seems to me that this is an advance so great that it should finally break down the prejudice against the idea of composite heliochromy which has grown out of the long series of failures of unscientific, complicated, and impracticable methods. With no more operations than are required to make an ordinary photograph, we now make a photograph that, as we are able to see it, reproduces nature itself, light, shade, and colour.

F. E. Ives.

GELATINO-CHLORIDE-OF-SILVER PAPER: ITS MANIPULATION.*

The Alum Bath.

Taking a print from the washing water, place it in the bath, being sure it is covered with the solution and free from air-bells; then watch the results. With a bath strong in gold the change will begin almost at once. With some baths the prints will rapidly turn to a bright yellow, and on to brown and purple, and, when arrived at the required tone or slightly deeper judging by transmitted light, are transferred with a good rinse in clean water to the fixing bath. It is recommended, however, to wash the Ilford P.O.P. for five minutes before fixing. In the case of a slow bath several prints may be toned at once, taking care to keep them in pairs face to face, as otherwise the toning solution will not flow between them; but they will cling together and tone unevenly. Toning may be stopped at any point desirable, and considerable variation is thus obtained. Should the bath become exhausted whilst in use, gold should under no circumstances be added whilst the prints are therein, or unequal toning will result. In the event of the bath containing too much gold, the edges of the prints may tone before the centre; an alum bath before toning will generally prevent this. The fixing bath is best made of one ounce of hypo to ten of water without the admixture of any other substance, and the print should be placed therein, face upward, stirred about, thoroughly wetted, and allowed to remain therein certainly not less than fifteen minutes. The toned prints may, of course, be saved and all fixed at once, and it is then best to arrest the toning by placing the print in a bath of salt and water; the former method will, however, generally give a better tone. The true tone of the print is not attained until it is properly fixed, a considerable loss of tone and strength often taking place on the first immersion in the fixing bath; but when fixation is complete this should return. It is undesirable to use too strong a fixing bath, as the tone of the prints may be permanently reduced. I have never yet seen any indication of frilling or blistering with these papers; but I conclude that it does sometimes occur, as we find so many formulæ for its prevention. If such symptoms are visible, and an alum bath be used as is generally recommended, the prints should be laid therein face downwards, and must be most effectually washed after the alum bath and before toning or fixing, as the case may be, or the sulphocyanide or hypo will be decomposed, and the prints will eventually turn more or less yellow. A good bath, I believe, is chrome alum, one part; distilled water, 150 parts, with the addition of ammonia, until a permanent precipitate is formed. It should be filtered, and three or four minutes in this bath will effectually harden the gelatine and enable it to maintain its enamelled or matt surface less impaired by wear. In washing the prints the object to be attained is to completely remove the hypo in the least possible time, for if the hypo be not illuminated the prints are unstable, and if washing be too prolonged, the gelatine will possibly partly decompose.

Combined Toning and Fixing.

There are many good washers on the market, and those perform their work best which rely upon a stream of running water entering at the top with not too much force, and draw off from the bottom below the prints. With a good supply of water and such a washer, about two hours should be sufficient. Effectual washing may also be carried out in a series of changes of water at short intervals, or the moisture may be several times squeegeed out upon glass, or other substance, with washings in fresh water in between. All formulæ for the removal of hypo by other agents should be studiously avoided, as by their means the salt is merely converted into other compounds almost as detrimental to stability, and is not eliminated. Combined toning and fixing baths, the defects of which I pointed out, probably owe their extended use to the saving of trouble attendant upon the loss of separate fixing; but some of them are stupendous mixtures, and I imagine the chance of failure is rather increased by this complexity. The following bath, as recommended by Liesegang, answers very well with all brands of paper:—

A.

Water	24 ounces.
Hyposulphite of soda	6 ,,
Sulphocyanide of ammonium	1 ,,
Acetate of soda	1 ,,
Saturated solution of alum	2 ,,

B.

Dissolve thirty grains of nitrate of silver in half ounce of water; add thirty grains of common salt, stir well till a white precipitate is formed; pour B into A, and leave it for a day. Then filter, and add the following solution:—

C.

Water	6 ounces.
Chloride of gold	15 grains.
Chloride of ammonium	30 ,,

The bath will keep for any length of time. It can be used over and over till the light half tones of the print become of a greenish hue, which is an indication that the fixing agent is exhausted, when it must be replaced by a fresh bath. A fresh bath may take an hour or more to tone to the violet shade; after having been used several times it will tone

* Concluded from page 348.

quicker. The bath recommended by the Blackfriars Sensitising Company for their paper is very similar, the saturation of the bath with chloride of silver, which is necessary to the proper working of all combined baths, is here obtained by putting in waste prints, scraps, &c.

Water	24 ounces.
Hyposulphite of soda	6 ,,
Sulphocyanide of ammonium	1 ,,
Acetate of soda	1½ ,,
Alum saturated solution	10 ,,

Fill the bottle containing this solution with scraps of sensitised paper, bad prints, &c., which have not been fixed. Filter; allow to stand for one day, then add—

Water	6 ounces.
Chloride of gold	15 grains.
Chloride of ammonium	30 ,,

With this bath the prints require no preliminary washing. The prints are plunged direct into the solution, and allowed to remain until the desired tone is arrived at. A good and simple bath is:—

Chloride of gold	6 grains.
Nitrate of lead	3 ,,
Sodium hypo	3 ounces.
Distilled water	20 ,,

This bath has the advantage of being free from alum. It is best in all cases, when mixing combined toning and fixing baths, to dissolve the gold separately, and neutralise it with powdered chalk, and afterwards to filter, and add to the other salts, which should also have been dissolved and filtered. The necessary saturation of the bath with chloride of silver, I have already alluded to. The final washing is, of course, the same as where two separate baths are used. The weakest point in the combined baths is the uncertainty as to how far the prints are being fixed; this will, after a time, show itself by a greenish tint in the white; the bath is then worse than useless. In toning with uranium and gold, the following is a good bath:—

Chloride of gold	4 grains.
Uranium nitrate	4 ,,
Chloride of sodium	60 ,,
Acetate of sodium	60 ,,
Distilled water	16 ounces.

Dissolving the uranium and gold in a little of the water, and neutralise with chalk.

Platinum may be used for toning, and according to Obernetter the following formula will render pure sepia tones:—

No. 1.

Chloro platinite of potass	15 grains.
Distilled water	1 ounce.

No. 2.

Neutral oxalate potass	2 ounces.
Phosphate of potassium	12 grains.
Distilled water	40 ounces.

Use two parts of No. 2 to one and a half parts distilled water, and one part of No. 1. It is essential that chloro-platinite of potassium be used, and not the chloride of potassium of commerce. The formula recommended by the Platinotype Company is also considered good:—

No. 1.

Oxalate of potash	5 ounces.
Monopotassic ortho-phosphate	3 ,,
Water	50 ,,

No. 2.

Potassium chloro-platinite	60 grains.
Water	2 ounces.

taking three parts of No. 1, one part of No. 2, and two parts of water. These baths will not keep more than a couple of days. The prints must have a preparatory washing, as already described, and be prepared for the toning bath by a final wash in distilled water. They had best be placed in the toning bath face upward, and, when the action is complete, must be thoroughly washed in cold water, made slightly alkaline with carbonate of potash or soda, and are fixed as before described. The prints having been toned, fixed, and washed, there are several methods of finishing them. I generally prefer to dry them preparatory to any farther operation, as I am inclined to think that they are easier of manipulation if not quite so saturated as when taken direct from the last bath. If, however, they have been treated with chrome alum, and it is desired to finish them with any other than the natural surface, they must not be allowed to dry, or no amount of soaking will render them soft enough for future manipulation. Drying must be spontaneous, and heat must on no account be applied; hanging them by clips to a string is a good method, or laying them over a couple of parallel rods or strings. Care must be taken that no dust settles upon them, especially dust from a dark room or laboratory. If left to dry thus, their natural surface will be equal to, or more shiny than, albumenised paper, and they may be thus trimmed and mounted. Should any deposit from the water appear upon the face of the print, it may be removed by wetting the print and gently rubbing the face with a tuft of cotton wool. The detail in the prints, when dry, will be considerably clearer than when wet, owing to the greater opacity of the paper.

Finishing the Prints.

The surface of the prints may be slightly reduced in shinyness by pressing them between sheets of blotting-paper before they are quite dry. They must not, however, be wet, or sticking will occur. To finish the prints with a matt surface, they may be squeegeed upon fine ground glass, such as should be used for focussing screens. The ordinary ground glass of commerce will not do, as it will show glazed specks. The glass must be thoroughly clean. An ordinary scrubbing-brush and Brooke's Monkey Brand will effect this in a few moments, and it can then be left to dry, or be dried with a cloth, and the surface be dusted over with a tuft of cotton wool dipped in powdered talc, otherwise known as French chalk, which in turn is removed by rubbing with a piece of clean silk or linen, so that no talc is visible. The prints, having been soaked for a few minutes, are then pressed into contact with the glass, using a roller squeegee and some little force, and a piece of clean paper on the back of the print to prevent tearing. The air must be entirely pressed out, and the prints will then adhere more closely to the glass; and, when dry, a piece of cartridge paper, or special waterproof paper, sold for the purpose, and cut to the exact size, is mounted upon the back. When the prints and their backing are thoroughly dry, they will easily peel from the glass support, just raising one corner with the edge of a knife. Should the prints refuse to move through the use of common or dirty glass, they may be taken off by soaking in a weak solution of hydrochloric acid and water. There is another method of matting the surface, which I have been trying lately, namely, by lightly rubbing the surface of the print with clean white pumice or other powder having a fine tooth. This is a vastly easier method, and, I think, as good. Prints which are lighter than desired are especially benefited by matting their surfaces, and will appear considerably stronger than if finished with a glossy surface. In like manner, prints may be given an enamelled surface by squeegeeing upon the best British polished plate glass. The plate glass must be carefully handled, or it will get scratched, it being comparatively soft after the removal of the surface in polishing. Polished or matt celluloid ebonite, tin-type plate, or enamelled metal plates may be obtained and used for the same purpose as glass, and these will not require the use of talc; but, in the event of the prints not stripping properly, a trace of sweet oil may be rubbed on and removed. The principal point is to let the prints get thoroughly dry before attempting to strip them off. The waterproof backing before mentioned is applied to facilitate mounting, as, if the prints are stripped from the supports without it, difficulty may be experienced in preserving the highly glazed or matt surface when the mountant is applied, and the wet strikes through the prints. The glass may also be prepared with wax and benzole in a somewhat similar manner:—Yellow resin, 36 grains; yellow wax, 24 grains. Two ounces of benzole formed into a solution and spread over the glass with a tuft of cotton wool, and then polished off with clean cotton wool. The print is floated face downwards in a dish of clean water, the plate inserted below it, and the two brought up and out of the water, and treated as before described. Gelatino-chloride prints are more difficult to mount than prints upon albumenised paper, but failure need never result if only ordinary care be exercised. Those prints which are backed with paper may very well be mounted with starch or similar mountant, made as thick as possible, taking care that no hard lumps are formed. If the prints are finished with a matt or brilliant surface, and do not receive a backing of waterproof paper, starch and paste are not suitable mountants, and recourse must be had to shellac and alcohol, or gelatine and alcohol. These may be bought ready prepared at most dealers, and if used with care the glazed or matt surface will be little the worse. If desired to manufacture, these mountants receipts are to be found in such books as The British Journal Photographic Almanac, &c. The exact position the print is to occupy should be marked upon the mount if there is a wide border, the print laid face downwards upon a piece of clean blotting-paper, and the mountant brushed rapidly over the back with a stiff hog-air tool. The mountants are mostly used hot, being stood in a basin of hot water. The mountants may also be applied to the edges only by laying a sheet of paper upon the back of the print, cut so as to show one-eighth of an inch margin all round, the mountant being brushed upon this exposed part; the prints must, however, be very slightly damp to allow of this treatment without after cockling.

Mounting.

Another method of mounting, exceedingly easy to work, is to squeegee the trimmed print upon glass, and when nearly dry to work some strong starch into the back with a stiff brush, and leave to dry, and then strip from the glass. The mount is then wetted with sponge and water, and the print laid upon a wet mount and squeegeed down. A solution of indiarubber may also be used for mounting round the edges, and may be bought ready prepared, but is liable to decay. If it is desired only to retain the ordinary surface of the paper, the simplest method is to soak the trimmed print for a few minutes in cold water, then taking a print lay face downward upon a sheet of paper, blot off the moisture from the

back, and apply a warm gelatine and alcohol mountant, lay the print in its position upon the mount, and on the wet face a clean sheet of note paper, and press down with a soft pad of clean linen, wetting if necessary. The points to be observed in mounting are, not to apply too much mountant or it will press out at the edges, and not to place the prints under pressure until almost quite dry. There is a considerable advantage in using the best prepared mounting boards, as many deleterious chemicals, amongst them hypo and acids, are used in the manufacture of ordinary cards. Spotting may be done with pigment mixed with gum arabic, and if carefully executed will not show.

I am afraid in reading this paper I have been going over ground which most of you are as well or better acquainted with than I am. Instructions for the process are scattered broadcast over the land, and any one who will read and carefully follow them out may be assured of good results. The mechanical part of the process requires only care to work it, and so long as it is done well, the less time occupied by it, the more effort may be concentrated into those operations, such as printing and toning, where there is opportunity for the use and display of artistic feeling and knowledge. The capacity for making brilliant prints by this or that process is, to my mind, as nothing compared with the power to use to the full those qualities by which we may easily render or alter to suit the requirements of taste the forms and values as they are often crudely represented upon our negatives, and in its capacity to fulfil these requirements I believe the gelatino-chloride process to be capable of holding its own against any other.

J. C. S. Mummery.

COMPOSITE HELIOCHROMY.

Listening attentively the other evening, and with much interest, while Mr. Ives discoursed on the above subject at the Society of Arts, the idea occurred to me how singularly Mr. Ives and earlier experimenters seemed to have missed one of the simplest mechanical and optical means of securing the superposition of the differently coloured positives which go to make the composite picture. A drawing was shown of the plan proposed by Antoine Hippolyte Cros, which was a most complicated arrangement of revolving mirrors, involving some most difficult adjustments. Mr. Ives' own system, as in his "helio-chromoscope," was not described, but is known to consist of a series of glasses, dividing and reflecting the images until they meet at the eyepiece; and the number of surfaces seemed, in practice as well as in theory, to involve a good deal of cleaning to avoid moisture and dust. It occurred to me that a simpler plan than either had been overlooked, and I suggested to Mr. Ives after the meeting that he might find a commercial solution of this part of his work in the following direction. Those who remember the Polytechnic of thirty-five to forty years ago will recollect the earliest forms of the Zoëtrope, or wheel of life, there shown. A disc, with slits, revolving before the reflected images of graduated pictures, gave the appearance of life and motion, since so well known in the Zoëtrope, Praxinoscope, &c.

It seemed to me that adopting this principle it would only be necessary to set the three positives equidistantly as the radii of a circle, the bases accurately directed to the centre, and to mount the film so arranged on a framework attached to a spindle carrying a disc with three slits adjusted to these pictures. The whole being then rapidly revolved by a suitable appliance, and viewed either direct or through a magnifying eyepiece, would, under the law of persistence of vision, produce a similar result to that of the wheel of life, with the difference that the effect would be combination of colour, instead of apparent motion. Some day, I have no doubt, when heliochromy has become a commercial line, this plan of working will be brought forward as something new. I hope no one, then, will try to patent the idea.

W. Bishop.

A NEW DRY PLATE.

Two inherent defects of most gelatine plates are a liability to the phenomenon of halation, due, as our readers are aware, to the intermingling of the high lights of a picture with the darker parts, caused chiefly by reflections from the backs of the plates, and an inability to allow of any considerable latitude of exposure with normal, or even in many cases with abnormal, development. With the object of obviating the occurrence of the first-named evil, and at the same time of producing a sensitive surface admitting of an extension of the scale within the limits of which almost any exposure will allow of a good negative being easily developed, Messrs. R. W. Thomas & Co. have produced a new plate—called the "Sandell" plate, after the manager of the firm—at whose works we recently had an opportunity of witnessing some comparative experiments intended to illustrate its special advantages.

The new plate consists of two or more films of different degrees of sensitiveness, a slow emulsion forming, as it were, the substratum, a quick one the top coating. In the experiments, the "General"—that is the new plate—which is intended for all ordinary purposes, was pitted against the firm's Extra Rapid plates, and a series of equal exposures, ranging from a tenth of a second to fifteen seconds, made in bright sunshine with a lens of a given aperture. One of each variety was developed at a time in a normal, unrestrained developing solution. The exposures proved to be excessive in all cases, the ordinary plates, after fixation, presenting an over-dense, burnt-up, foggy appearance, suggestive of the impossibility of converting them into good printing negatives. The surfaces of the negatives on the "General" plates were, before fixation, extremely foggy; but, in contradistinction to the others, the images were not forced through to the backs of the plates, and, by transmitted light, could be seen to have retained due vigour and gradation, and proper density. After fixation both sets of negatives were "cleared" in a ferridcyanide bath. Those on the ordinary plates, however, still preserved the worst effects of over-exposure, such as flatness of image and general fog, the latter being very marked where the high lights met the shadows. On the other hand, the negatives on the "General" plates came out extremely brilliant and clear—full of sparkle, in fact—of excellent printing density, and having an admirable modelling of image. Indeed, we found it a difficult matter to differentiate between the negatives on the score of exposure, which, as we have indicated, had a range of from 1 to 150—a severe test.

The "Sandell" plate should simplify the difficulties attendant upon exposure, and will, doubtless, enable many a negative to be saved which if taken on an ordinary plate and very much over-exposed, would be lost.

"OPTIMUS" PRIZES.

Prizes to the extent of a hundred guineas for productions by the lenses manufactured by the "Optimus" (Perken, Son, & Rayment) Company remind one of enterprise displayed by some transatlantic firms, although never to our knowledge have these firms carried out the idea to quite such an extent as that manifested by the English firm.

This competition is open to all, whether amateurs or professionals. The conditions are very plainly laid down as follows:—1. Every prize-winner shall be required to make an affidavit that his negative has been produced by the aid of a lens bearing the trade mark "Optimus," and name, "Perken, Son, & Rayment" engraved on the mount, within the given period, and shall produce the lens if called upon. All prints sent in to this competition shall become the property of Messrs. Perken, Son, & Rayment. The negatives of the prize prints shall also become their property. 2. That every print must be from a negative produced since January 1, 1892. 3. The artistic trimming of prints shall be allowed, but in all cases the full size of the negative must be stated on the face of mount and entry form. 4. Enlargements or prints from enlarged negatives will not be admissible. 5. The whole work must be done solely by the competitor. 6. All prints shall be mounted, and bear on the face of the mount in the middle, half an inch below the base of the picture, a written or printed title, and on the back a *nom-de-plume*. The mount must not project more than one-third of the picture on each side; for example, the mount for a print measuring $7\frac{1}{2} \times 5$ must not measure more than $12\frac{1}{2} \times 8\frac{1}{2}$ inches. 7. With each print must be enclosed an envelop bearing on the outside the *nom-de-plume*, and inside an entry form, duly filled up, bearing competitor's name and address. 8. All prints and entry forms must be received by October 31, by E. J. Wall, 1, Creed-lane, E.C., and must be marked outside "'Optimus' Competition."

The Classes are:—1. Landscape, with and without figure. Sub-class A, 7×5 and under; sub-class B, $8\frac{1}{2} \times 6\frac{1}{2}$ and over. 2. Seascape. Sub-class A, 7×5 and under; sub-class B, $8\frac{1}{2} \times 6\frac{1}{2}$ and over. 3. Portraiture and figure study. Sub-class A, 7×5 and under; sub-class B, $8\frac{1}{2} \times 6\frac{1}{2}$ and over. 4. Instantaneous work, including also hand-camera work, limited to 5×4 and under.

The prizes offered to each successful competitor are such as must prove exceedingly tempting, and they are so arranged that each prize winner may select from them any one or the other that suits his fancy or requirements, all being of the same value, viz., 15*l*. each.

Set A, 10×8:—Rayment camera and two double dark slides. "Optimus" rapid view lens. "Optimus" tripod stand. "Optimus" focussing magnifier and focussing cloth. "Optimus" collapsing waterproof case.

Set B, $8\frac{1}{2} \times 6\frac{1}{2}$:—Rayment camera and three double dark slides. "Optimus" rapid rectilinear lens. "Optimus" tripod stand. "Optimus"

focussing magnifier and focussing cloth. "Optimus" leather case with lock and key.

Set C, 6½ × 4½:—Rayment camera and three double dark slides. "Optimus" euryscope lens. "Optimus" plunge shutter. "Optimus" fourfold tripod. "Optimus" focussing magnifier and focussing cloth. "Optimus" waterproof case with lock and key.

Set D, 3½ × 3½:—"Optimus" hand or detective camera, including six dark slides. "Optimus" rapid euryscope lens and shutter. "Optimus" enlarging apparatus, ornamental mahogany body, lined with metal, patent focussing adjustment, with six-inch compound condenser, also a four-inch for the projection of lantern slides.

Set E.—"Optimus" scout field-glass, with aluminium body. "Optimus" obique hand camera, with single view lens, shutter, and three double dark slides. "Optimus" photographoscope, a very handsome table ornament, having mechanical contrivance for displaying a number of cabinet pictures one after the other in endless rotation.

Set F.—Superior aluminium telescope.

It is, of course, necessary that each competitor make an affidavit that the picture was actually taken by an "Optimus" lens, the number of which, as engraved on the mount, must be given, and that the whole of the work of exposure, developing, printing, toning, and mounting was done by him or her since January 1 of the present year.

We have seen and examined the various prizes, and can vouch for their being, in every sense, first-class. Messrs. Perken, Son, and Rayment's enterprise should produce a most interesting competition.

The "Optimus" Universal Lens Flange.

The difficulty of attaching the multifariously-flanged lenses to a camera front is one on which we have many times written. We therefore hail with delight the introduction of any piece of mechanism which will enable this to be done with the maximum of efficiency and the minimum of trouble.

An appliance which is now about to be introduced under the name of the "Optimus" Universal Lens Flange meets with our warmest approval, as it must, with all who use a variety of lenses and do not care to carry with them a separate camera front for each. By this universal flange adapter, which is shown in the cut, having been screwed on the camera front in the usual way, we now possess a means of instantaneously and firmly attaching any one of our numerous series of lenses and changing them at will. The movements to attain this end are not only the most rapid but also the most simple yet contrived. This will be very readily understood if we say that the little arrangement is an ingenious application of the bayonet catch.

Three semicircular recesses are made on the margin of the lens flanges. These recesses correspond with three internal projections on the universal flange. The particular lens about to be used is pushed into the aperture of ring A on the cut. The lens being held firmly, about one-eighth of a revolution is described, when it will be found that rigid contact has been established between lens and camera. A reversal of the movement releases the lens, and others may be consecutively connected.

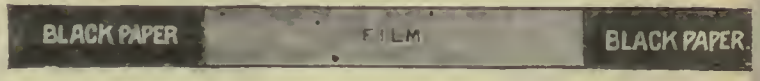
Those carrying with them a variety of lenses will hail this new flange with satisfaction.

NEW KODAKS.

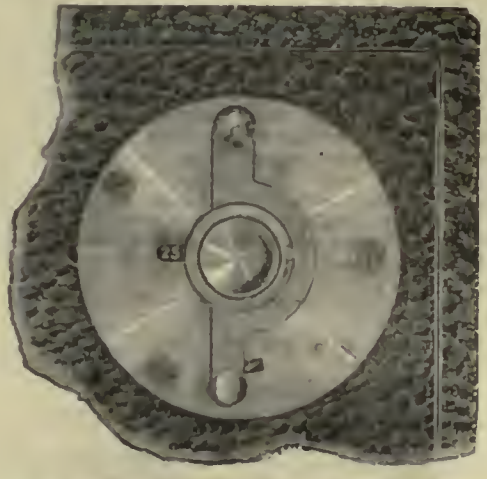
During the present week the well-known "Kodak" of the Eastman Company has entered upon a new, nay, a revolutionary stage of existence. Hitherto it has been manufactured in such a form as necessarily represented a price which, although moderate considering its get-up, was yet in excess of what many might be able to afford; but by discarding such refinements as Russia leather, morocco, and their cognates, and presumably by improved machinery in the production of the instrument, the Company now introduce a series of Kodaks so low in price as to beggar all preconceived ideas as to their cost.

The new series is known as the A B C Kodaks, and, as the prospectus says, "are designed especially for a very large and increasing number of amateurs, who do not care to purchase an expensive instrument. The letters A B C refer primarily to sizes, but they may be taken, in another sense, to indicate the great value of these instruments for beginners; they are extremely simple in construction, and will supply a want long felt for a really well-made camera of great capacity, enabling the beginner to commence at the A B C of Photography, and produce good results." The retail price of this series varies from twenty-six shillings to sixty-five shillings, according to size, a small advance on this price conferring the advantages of having a focussing arrangement and a leather-covered body, fitted with spools for reloading *in daylight*, a recently introduced improvement, which renders one independent of a dark room when *en route*.

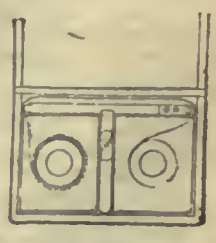
The power of reloading in daylight is one of inestimable value. The general principle is this: attached to each end of the sensitive film is a band of black paper, which, being wound round the film, prevents the



admission of light to it. It can therefore be handled in open daylight. The operation of charging the spools can be performed out of doors, by—after the twenty-fourth exposure has been made, and before the Kodak has been opened—pushing the register lever to the right, and winding the key, the operation being repeated until no more material can



be obtained. The empty spool taken from the Kodak being placed alongside (we quote from the directions), take the end of the paper protruding



from the fresh spool box, and draw it over to meet the paper on the empty spool, and fasten them together by moistening the gummed edge of the fresh spool. Allow the gummed edge to dry for five minutes.

Replace the spool boxes in the roll-holder, slotted ends down, the full spool at the left, and the film passing over the exposing board to the box containing the empty spool.

Replace and screw down the lid, and put the holder in its place on the camera.

The combination of advantages embodied in the new Kodaks should secure them a large share of favour, the facility for changing the spools in daylight being a boon of inestimable value.

CASTLE WEMYSS AMATEUR PHOTOGRAPHIC EXHIBITION.

The second Exhibition, exclusively for amateurs, was held at Castle Wemyss on Friday and Saturday, May 27 and 28.

This Exhibition is quite unique in its way, being got up, advertised, and conducted by a lady, Miss Burns, of Castle Wemyss, who is herself an enthusiastic and successful photographer. In the centre of the castle grounds, in a winter tennis hall, the Exhibition was located, this hall possessing plenty of space and being extremely well lighted.

Miss Burns, who takes upon herself all the responsibility of the undertaking, must feel highly gratified at the hearty response made to her circulars, for, although in quantity the number of exhibits sent in was scarcely up to those sent in on the first occasion, the quality showed a much higher standard of merit.

One thing that militates against a much larger show of exhibits at this Exhibition is, we believe, the limited time the exhibitors have to prepare their work. This cannot well be avoided, for the lady cannot date forward the same as a committee working up an exhibition, as it is only when she has a few clear weeks that the pleasant pastime can be indulged in and worked out.

Still we are of opinion that, if three or four months were allowed to prepare the work, the hall would be filled to overflowing with exhibits. The long distances that many of the present exhibits have come is surprising, and speaks well for the future.

The Judges were Messrs. Francis Powell, John Fergus, George Mason, and H. E. Gordon.

The following is the list of awards:—Portrait or group (photographer under two years' experience).—First prize, silver medal: Mrs. Mceta Pollard, for *Miss Nettie Beattie;* second prize, bronze medal: none awarded. Landscape or seascape (photographer under two years' experience).—First prize, silver medal: Mr. Pollock, for *In Clandeboye Demesne;* second prize, bronze medal: Miss Martin for *The Fruin.* Portrait or group.—First prize, silver medal: Mr. Evans, for *Only a Street Arab;* second prize, bronze medal: Mr. J. Chamberlain, for *Eastern Fantasia.* Landscape or seascape ($8\frac{1}{2} \times 6\frac{1}{2}$ and over).—First prize, silver medal: Mr. Austin, for *Off to the Plough;* second prize, bronze medal: Mr. Stewart Smith, for *Kelly Sawmill.* Landscape or seascape (8×5 and under).—First prize, silver medal: Mr. Martin, for *Loch Linnhe;* second prize, bronze medal: Miss Brock, for *The Fruin.* Instantaneous.—First prize, silver medal: Mr. Martin, for *Swans;* second prize, bronze medal: Mr. A. Watson, for *Yacht.* Animal study.—First prize, silver medal: Mr. Austin, for *Cooling Waters;* second prize, bronze medal: Mr. F. Mackenzie, for *Highland Cattle.* Enlargement.—First prize, silver medal: Mr. Austin, for *Winter;* second prize, bronze medal: Mr. Morison, for *Watering the Horses.* Lantern slides (set of six).—First prize, silver medal: Mr. Arch. Watson; second prize, bronze medal: Mr. D. Cunningham and Mr. Austin (equal).

Meetings of Societies.

MEETINGS OF SOCIETIES FOR NEXT WEEK.

Date of Meeting.	Name of Society.	Place of Meeting.
June 7	Exeter	College Hall, South-street, Exeter.
,, 7	Glossop Dale	Rooms, Howard-chambers, Glossop.
,, 7	Herefordshire	Mansion House, Hereford.
,, 7	Lewes	Fitzroy Library, High-st., Lewes.
,, 7	North London	Wellington Hall, Islington, N.
,, 7	Oxford Photo. Society	Society's Rooms, 136, High-street.
,, 7	Rotherham	
,, 7	Sheffield Photo. Society	Masonic Hall, Surrey-street.
,, 7	York	Victoria Hall, York.
,, 8	Leicester and Leicestershire	Mayor's Parlour, Old Town Hall.
,, 8	Munster	School of Art, Nelson-place, Cork.
,, 8	Photographic Club	Anderton's Hotel, Fleet-street, E.C.
,, 8	Reading	
,, 8	Stockport	Mechanics' Institute, Stockport.
,, 9	Birkenhead Photo. Association	Association Rooms, Price-street.
,, 9	Bradford Photo. Society	50, Godwin-street, Bradford.
,, 9	Hackney	Morley Hall, Triangle, Hackney.
,, 9	London and Provincial	Champion Hotel, 15, Aldersgate-st.
,, 9	Manchester Photo. Society	36, George-street, Manchester.
,, 9	North Kent	Gravesend.
,, 9	Oldham	The Lyceum, Union-street, Oldham.
,, 10	Cardiff	
,, 10	Holborn	
,, 10	Ireland	Rooms, 15, Dawson-street, Dublin.
,, 10	Maidstone	"The Palace," Maidstone.
,, 10	Richmond	Greyhound Hotel, Richmond.
,, 10	West London	Chiswick School of Art, Chiswick.

LONDON AND PROVINCIAL PHOTOGRAPHIC ASSOCIATION.

May 26,—Mr. J. Weir Brown in the chair.

Meteorological Photography.

Mr. A. W. Clayden, M.A., the Secretary of the Committee on Meteorological Photography, appointed by the British Association, gave a brief discourse on this subject, illustrated by numerous lantern slides, first of all describing and exhibiting the camera he uses for this class of work. This consists of a swing camera, with a revolving black glass mirror inclined to the axis of the lens. The mirror being arranged to extinguish the polarising component from blue sky, there was, said Mr. Clayden, remarkable detail when one looked at a cloud on the screen, and this was partly due to the extraction of the polarised component of the blue light, and a good deal to the diminution of the brightness of the image. It enabled one to judge the exposure carefully. Having pointed out the objects of meteorological photography, he said that, when he began photographing clouds, he endeavoured to find out whether there was any kind of plate which had special advantages for this particular purpose. He had found there was not very much to choose between the various kinds. The Committee wished photographers to take photographs of thunder clouds, &c., at short intervals, so as to have successive photographs in order to be able to study the development of one form of cloud out of another, and in its various transition forms. In connexion with lightning photography, a number of points had never been cleared up, as, for example, the cause of the black flash.

Mr. Clayden then exhibited a number of lantern slides of cumulus and cirrus clouds in various stages of formation, together with several slides of lightning flashes. Some of these were taken with a hand camera, and the fact that some of the flashes took a triple form led him to question whether he had not moved the camera during the exposure. In connexion with some pictures of the black flash, the phenomenon of reversal was shown. He had tried to get reversal with the electric spark, and had succeeded by allowing diffused light to have access to the plate after exposure. Diffused light on the plate before exposure did not produce reversal.

Mr. W. E. DEBENHAM, in reference to a complaint of Mr. Clayden as to the granularity of some of the pictures which were intensified with mercury, said the granularity would not appear if the plates were kept well moving during intensification.

Mr. J. E. SMITH asked Mr. Clayden if he had ever succeeded in photographing a rainbow!

Mr. CLAYDEN had done so, but it was not a very brilliant image.

Mr. G. W. ATKINS, in connexion with Mr. Clayden's suggestion as to successive discharges of lightning having produced three images of a signal-post in one of the pictures shown, said that on one occasion during a flash he had seen a signal-post in three different positions.

Mr. DEBENHAM pointed out that the fact of the plates not having been backed was sufficient to cause reversal of the image in some of the pictures, and said it was extremely desirable that in these experiments backed plates should be used.

After some further discussion, a vote of thanks was passed to Mr. Clayden.

Mr. ASKEW exhibited his combination oil lantern, which is rapidly set up on an ordinary tripod. The whole packs up very compactly, and may be carried on an ordinary bicycle. It is chiefly intended for village use.

The meeting then terminated.

Holborn Camera Club.—May 27, Mr. T. O. Dear in the chair.—A large number of slides which had taken prizes in a competition were passed through the lantern, followed by some by Messrs. Ebsworth Cobb, and Miller.

Harlesden and Willesden Photographic Society.—May 24, Annual General Meeting.—The following officers were elected:—*President:* Mr. John Naylor.—*Council:* Messrs. T. Clapton, Pay, C. Winterbon, H. Dale, and Lyon.—*Hon. Treasurer:* Mr. Seed.—*Hon. Secretary:* Mr. W. E. Woodbury, 23, Fairlight-avenue, Harlesden, N.W. An excursion to Stanmore, under the leadership of the President, Mr. Naylor, will take place on Saturday, June 4, the members to meet at the booking-office, Willesden Junction, at 2.30 p.m.

Bath Photographic Society.—May 28, the first excursion of the season.—The party travelled to Holcombe. Here a disused old church was found, possessing a very perfect specimen of a Norman doorway, supposed to have been taken from some older buildings, and, among other things, some curious epitaphs in the churchyard, dated 1800. Here is one:—

"Come read your doom,	One day with me
And see you must	Lye in the dust."

Norton Hall is very pleasantly situated in extensive grounds, adjacent to the main road through the coal districts, many portions of this road being of Roman construction. Besides extensive views of the famous Mendip range obtainable from the house and grounds, many picturesque scenes were depicted as the party rambled over the domain.

Birmingham Photographic Society.—May 26, Mr. G. F. Lyndon in the chair.—SIX new members were elected. Samples of Berkeley's "Theonine" and one of Mawson's "Sensible" focusing cloths were laid on the table. Mr. A. J. Lesson gave a demonstration and paper on the *Preparation of Home-salted and Sensitised Paper by the Ammonia Nitrate of Silver Process.* The demonstrator went through the different operations of salting, sensitising, toning, fixing, &c., showing very clearly the manner in which the work is done. Mr. LESSON said one of the advantages of salting and sensitising one's own paper is that paper suitable for all subjects is easily prepared, whether the detail is wanted to be microscopically sharp or whether it is required that it shall be softened down in the charming manner obtainable by means of the rough paper. There will, of course, always be two opinions about the rendering of detail; but a great deal depends upon the class of subject which is represented and the fancy of the printer. The paper to be used—the paper I generally use—is Whatman's hand-made water-colour paper; but so long as it is pure, of an even surface, will stand plenty of washing, and is of a good colour, it is immaterial whose make is used. Mr. Lyonel Clark recommends Reeves & Son's Arnold's unbleached; but it is not necessary to use paper at all, for silk, satins, wood, &c., may be used instead. Whatman's have a number of papers with different surfaces, from the very smooth to the very rough, so that all one has to do is to suit the paper to the negative. The colours obtainable is a great feature of this process; brown, reddish-browns, sepia, purple, black, &c., are very easily acquired, and there is no difficulty with whites, except, perhaps, at the edges, and for that reason I sensitise a little larger-sized piece of paper than I require, so that the outside edge may be trimmed off. An imperial sheet of Whatman's paper will cut up into six pieces 10×8 and three pieces 10×6. These sizes allow for masking off a margin when printing from whole-plates or under. I ordered from a local mount-maker a number of masks cut to required sizes, so that I can at any time adjust the mask to the size of the picture required. The salting solution I generally use is made up as follows:—Chloride of ammonium (not sal ammoniac), 7 parts or 2 drachms; gelatine, 12 parts or 3½ drachms; water (warm), 1000 parts or 36 ounces. The chloride of ammonium is put into the solution when nearly cold. The prints are placed in this, and brushed over with a tuft of cotton wool, and allowed to lie immersed till the paper is fully expanded. They are then taken out separately and hung up to dry in a warm room. If preferred, the prints may be floated for about three minutes on the bath singly. Always use the bath pretty warm, or the gelatine will set in patches. Thin negatives require more ammonium chloride than dense ones. Rapidity of printing is obtained by the use of more salt with the gelatine; it also makes a more vigorous print. The paper now contains ammonium chloride; but, as this is insensible to the rays of light, silver, in the form of a nitrate, is applied. This combines with ammonium chloride, the latter giving up its chlorine to the silver, forming chloride of silver, and the ammonia takes up the nitrogen, forming a soluble salt, ammonic nitrate. This silver chloride darkens on being exposed to the light. The sensitising bath is made up as follows:—Nitrate of silver, 2 parts or 3 drachms 12 grains; distilled water, 10 parts or 2 ounces. (It is not absolutely necessary that the water should be distilled, but the purer the water the better.) The nitrate is dissolved in the water, and is then converted into "ammonia nitrate of silver" by adding ammonia drop by drop till the precipitate first formed is redissolved. It is then divided into two equal parts, to one of which add nitric acid till the litmus test shows that it is slightly acid. The two halves are then mixed, and the bulk made up with water to twenty parts, or four ounces. The bath need not be protected in the slightest from light; in fact, silver baths are often improved by being sunned. The solution is now brushed over the paper on the right side. I always place the paper on a large sheet of plate glass inclined a little by being placed in a large porcelain dish, the bottom of the glass resting on the bottom of the dish against one side, and the opposite side of the dish supporting the glass plate. On this I place a sheet of blotting-paper, and then the paper to be sensitised. The blotting-paper absorbs any solution which may come over the sides of the paper, and, should any quantity flow off, the dish prevents it reaching the table. The solution is then brushed over the paper in broad sweeps by means of a good-sized camel's-hair brush (avoid brushes bound with wire), commencing at the top and working from left to right till the bottom is reached. The paper is then turned at right angles to its previous position, and the brushing repeated so that it will cross the lines of the other coating; it can then be hung on a peg to dry. This process is then repeated, as the nitrate of silver must be in excess. This paper, when prepared, will not keep like the ordinary sensitised paper of commerce, but should be sensitised, toned, and fixed in the day, or within forty-eight hours at longest. Should it be wanted to be kept a time before being toned, a different formula will be required. Mr. Clark recommends the following:—Nitrate of silver, 60 grains; citric acid (crystals), 25 grains; water, 10 ounces. As in albumenised paper, the citrate of silver keeps so much better than the nitrate, as it is the free nitrate which discolours the paper. One can tone with almost any toning bath, the prints toning much quicker than the ordinary silver paper; in fact, for the following bath, which I always use, the tone varies between forty-five seconds for a warm brown to three minutes for a purple black. Toning bath:—borax, 30 grains; chloride gold, ½ grain; water (warm), 6 ounces. This bath can be used at once, and while warm; no appreciable difference will be noticed in the colour until put into the fixing solution, when the colour instantly begins to change to the tint required. After washing, the print is placed in a fairly strong hypo bath for ten minutes, and it is then as well to place it in a second hypo bath, so as to be quite sure all the free silver is removed. The prints are then washed thoroughly, and dried by being hung up by one corner, previous to which I place them between blotting-paper to absorb all the water from the surface of the print. These prints lend themselves to spotting very easily, as the colour is not repelled, as is the case with albumenised paper, and the colours are easily obtained. In conclusion, I would draw your attention to a few notes it is as well to bear in mind. It is best, if possible, to salt and sensitise the paper in double-length strips. One advantage of Whatman's paper is that the name is confined to one quarter sheet. Don't make enough salting solution to last more than a month, or it will rot. Keep the bath warm while salting. If rapidity or vigour is required, use more salt. Once sensitising is often not sufficient; repeat the process, in order to be on the safe side. Don't dry it too quickly. Sensitise, tone, and fix, if possible, in one day, as by so doing cleaner prints are obtained. The pluckier the negative, the richer the tone. Wash thoroughly. Stains of silver may be removed by salt, hypo, or cyanide of potassium. Be sure the paper is perfectly dry before placing it in the printing frame, or it will spoil the negative. Print deeper than is usual for albumenised paper. Wash in a change or two of water before toning; wash well after toning and before fixing; wash very thoroughly after fixing.

Liverpool Amateur Photographic Association.—May 26, Mr. W. Tomkinson, the President, in the chair.—Two new members were elected. Mr. SCHIERWATER introduced a discussion on *Film Photography*, giving his experience of the use of films by different makers, and showing an ingenious carrier for the dark slide, and also one for the developing dish of his own construction. Mr. A. W. BEER stated that, in a tour on the Continent last year, he, with a friend, used twenty-four dozen 10×8 films with most satisfactory results, and hoped to do the same again this year. He had not the least difficulty with development, as by keeping the bottom of the dish wet the film would lie perfectly flat by suction. Mr. PAUL LANGE expressed his intention of taking thirty dozen 5×4 to Norway with him next week, the weight being six pounds instead of half hundredweight, which it would have been if he had taken glass. The President then called upon Mr. John Carbutt, of Philadelphia, the well-known manufacturer of Carbutt's films, who, in passing through Liverpool, had kindly accepted the Secretary's invitation to be present at the meeting. Mr. CARBUTT said that films were rapidly coming into favour with amateurs for outdoor work, because they were now quite reliable. The defects in the earlier films put upon the market were found to be caused entirely by the chemical composition of the celluloid; but, after numerous experiments, this had now been remedied. Mr. Carbutt exhibited some large prints, about four feet by two feet, which had been taken direct upon films with a panoramic lens. He also showed two very ingenious cameras, the "Genie" and the "Henry Clay." Mr. Archer exhibited an apparatus for drying negatives, the "Cytox" hand camera, and the "Eiffel" stand for half-plate camera, weight sixteen ounces. An exhibition of lantern slides followed.

Correspondence.

☞ *Correspondents should never write on both sides of the paper.*

HELIOCHROMY.—ALBERT SCOTT AND DR. VOGEL.

To the EDITOR.

SIR,—Mr. Albert Scott, p. 345, makes some erroneous statements, which he has made before, and which I duly corrected, but which I must correct again because he has repeated them.

1st. My original demonstration of composite heliochromy with the triple lantern, in February, 1888, was *not* carried out with "red, yellow,

and blue glasses," but with red, green, and blue-violet. 2nd. Three lanterns were *not* employed, but *one* lantern, built expressly for this purpose, with three optical systems close together, and a triple jet, *which is the same arrangement that I use to-day.* 3rd. I did *not* use three slides, but *one* slide carrying the three pictures. 4th. My earlier experiments, as far back as 1881, were with a single sensitive plate for the three pictures, which were made by simultaneous and equal exposure behind three lenses; and that plan I had to abandon as worthless long before I published anything relating to this subject. It fails now in Mr. Scott's hands, as it failed in my hands ten years ago, because the three images, being unlike, will not register on the screen.

Mr. Scott's only original idea in connexion with this subject, is that of a lantern employing a single source of light for projecting several pictures —an ingenious plan, but quite unsatisfactory with the limelight.

Dr. Vogel (p. 351), instead of acknowledging errors which I clearly pointed out in his last communication, makes another false accusation, and fresh errors. I repeat that the Franklin Institute gave Dr. Vogel a full hearing in the matter referred to, through correspondence with Professor Himes, who was one of the most active members of the Committee in charge of the investigation, and very friendly with Dr. Vogel. Dr. Vogel received the statement I have mentioned, and I believe his comments upon it are now on file, with the other papers relating to the case, in the library of the Franklin Institute. Professor Himes signed the report crediting me, not with the "invention of orthochromatic photography," *which Dr. Vogel has good reason to know I never claimed*, but with the publication of the first practically successful method, years before Dr. Vogel announced that he had just "solved the problem" with eosine collodion sensitive plates and the yellow screen, a method that gave inferior results.

Mr. Bothamley's statement of Dr. Vogel's principle will be found in the *Photographic News*, 1887, p. 568, and sustains my statement that he contemplated the use of not less than five separate negatives and colour prints.

The statement that "the method of working with three negatives, claimed by Mr. Ives, is an old one," is something else than merely inexcusable, in view of the statements I have made in each and every paper I have published upon this subject. Facts and references are given in my paper on "Composite Heliochromy," in the *Journal of the Society of Arts* of May 27.*

Dr. Vogel persists in ignoring the fact (which he recognised in a characteristic way at the time) that my method was published in 1888, with particulars of the production of colour prints—two years before Dr. Vogel now claims to have exhibited some colour prints, which, so far as I can learn, were never brought to the attention of the photographic world.

I know very well that the only true complementary colour of any dye is the mixture of light rays absorbed by that dye, and that Dr. Vogel's idea, *according to his own interpretation of the action of colour sensitisers*, represents the use of colour prints exactly complementary to the colour of light which has acted to produce the negatives. Dr. Vogel may assert the contrary, and may find some to accept him as an authority upon this subject, but that will not alter the facts.

Dr. Vogel has a right to quote, and spread, and commend the only unfavourable expression of opinion of my lantern projection process he has been able to find in print, and to ignore the heliochromoscope altogether.—I am, yours, &c., FRED E. IVES.

London, May 30, 1892.

MR. LYONEL CLARK AND THE LONDON AND PROVINCIAL PHOTOGRAPHIC ASSOCIATION.

To the EDITOR.

SIR,—I notice in a report appearing in your columns that I am mentioned as being the examiner who set the question in the last examination paper of the City and Guilds of London, as to the best means of ascertaining when a silver print is properly fixed. Will you permit me to point out that, although appointed to the post, my duties in connexion therewith do not commence until the ensuing season, and that therefore I had nothing to do with the setting of this very practical question that has aroused so much interest.

I mention this fact, as the Society in question wrote to me saying that the query had been put at one of their meetings and had been referred to me, but not stating or in any way showing that they were addressing me as the examiner who had set it; and indeed it was only from a perusal of your columns that I discovered the existence of this erroneous impression.

The matter has become slightly complicated from the fact that, believing I was written to as a private individual who had given some attention to the subject of printing in salts of silver, I was very pleased to give the results of my experience in this branch of the subject to the Society, and accordingly sent them a few rough notes on the subject.

If these notes should come before the eyes of any of your readers, they may, under the erroneous impression that I was the examiner answering his own question, give them an official *cachet* which they do not possess, and I should be glad to avail myself of the opportunity offered by your columns to state that these are my private opinions, given without the knowledge that the question had ever been publicly asked in the Guild's examination, but merely put forward to be of what benefit they might to my fellow-photographers.—I am, yours, &c., LYONEL CLARK,

11, *Victoria-street, London, S.W.*, *Hon. Librarian, Camera Club.*

May 25, 1892.

* Mr. Ives' paper, to which reference is here made, will be found on page 357, *ante*.—ED.

PHOTOGRAPHIC LENSES.

To the EDITOR.

SIR,—There is an omission in the report of the discussion on the *Concentric Lens* at the Society's rooms on May 24.

I was stated to say that "one of the greatest difficulties in the construction of photographic lenses was the cure of colour." I said "the cure of *spherical aberration* with colour." This, known as "under-correction," is associated with a degree of positive aberration that cannot be separately corrected in a telescope, which must ever remain faulty, unless all colour is eliminated.

On the other hand, in the photographic lens with the presence of this colour, irrespectively of which we can correct spherical aberration alone, by varying the thickness of the glass, or by an adjustment of the distance of the component lenses of the system, we can thus obtain a surprising degree of distinctness in the image, that almost equals telescope definition. —I am, yours, &c. F. H. WENHAM.

DEPTH OF FOCUS.

To the EDITOR.

SIR,—It is a matter of surprise that a gentleman of Mr. F. H. Wenham's more than European reputation should write setting up a claim for "Depth of Focus" for a particular lens, thus practically asserting the insufficiency of the formulæ in the text-books, which give only the aperture and focal distances as factors, without being prepared to show that a difference in this respect between two otherwise similar lenses is at least possible.

In the discussion which took place on Tuesday, the 24th inst., Mr. J. Stuart admitted that for central rays the lens in question possessed no greater depth of focus than any other corrected lens, and that it was impossible it should have. He, however, still claimed that the marginal rays being better defined than with other lenses, there was a greater distance within which a certain sharpness could be obtained. This comes within the case of the possible apparent exception referred to in my former letter, and is more properly described simply as better marginal definition.

It is to be hoped that the present incident will do something towards expediting the extinction of the fancy, once cherished by many photographers, that depth of focus is a quality existing in some lenses more than others, independent of equality in aperture, focal length, and fineness of focus, or absolute defining power.—I am, yours, &c.,

May 30, 1892. W. E. DEBENHAM.

PHOTOGRAPHIC PRINTERS.

To the EDITOR.

SIR,—Your correspondent, "Unfortunate," complains of not being able to find a situation to suit him, and as I am *another* unfortunate who has not been able to find a printer to suit me, I thought that a few remarks from a brother in distress might not be devoid of interest.

First of all, I shall be glad to give immediate employment to "Unfortunate," promising him a permanency, moreover, if he will but print me one dozen albumen prints or whatever order he has, from each negative *alike* in depth and colour, is able to vignette well and ensures perfect fixation and subsequent conscientious and careful washing in repeated changes of water. To such a workman I shall be ever grateful, and I further promise your correspondent, and you Mr. Editor, that I will report progress to your readers after a trial for a month or two, endeavouring to be just to him, the public, and myself. I may say that I had one printer who served his apprenticeship with me, after which he *remained* for several years (seven in all), a better workman could not be found. Before and after this, my unfortunate experiences with printers were such as to make me often give way to a sinful longing for a land were everything is toned and fixed by spiritual agency. I have written enough on this subject in the pages of this JOURNAL and its ALMANAC, (see ALMANAC 1888, page 336), to show that there are two sides to this question, and I am sure a majority of employers will support my statements.

Any "unfortunate," who is not afraid of work and able to cope with an ordinary amount of work, changing each print when done and not waiting till the whole batch is completed, may be sure to find employment, but I am emphatically of opinion, that the peril lies in *keeping* the same. If printers would bear in mind that it is the result of their labour which passes directly into the hands of the customer, and that they have it in their hands to make or break a business if left to themselves, things might be different.

At the present time there can be no doubt, however, that the supply exceeds the demand, but I do not think this would be the case if printers would look upon themselves as skilled workmen and not as automata.—I am, yours, &c., J. HUBERT.

N.B.—I have always found vacancies advertised in your JOURNAL.

May 30, 1892.

To the EDITOR.

SIR,—I notice in your last issue a letter from a photographic printer complaining that he cannot get work, and you seem rather to endorse the view that that class of work is hard to obtain. Of course, it is difficult in any trade for a man to obtain work unless he be both smart and energetic; but the number of applications that we get for smart platinotype printers proves conclusively that a good man need never be out of employ.

Of course, if a man is content to stick to silver printing and antiquated processes of that kind, he cannot expect to keep his head above water. But the demand for really good workers is enormous; at the present moment we are are asked to send a good man out to Philadelphia, and the writer states that he could find places for dozens of good platinotype printers; but, out there, a man must not only be a good worker, but must be pushing and able to move with the times.

It is as true, in the photographic trade as in every other, that no good worker need ever be out of work; it is only the incompetent or the lazy who get left in the race of life.—I am, yours, &c.,

The Platinotype Company, ERNEST J. HUMPHERY.
29, Southampton-row, High Holborn, London, W.C., May 31, 1892.

CORRECT EXPOSURES.

To the EDITOR.

SIR,—I was expecting that a better optician than I can claim to be would reply to Mr. Michael's letter on this subject on p. 335, but as no such answer has appeared, I venture to give the result of my experience.

It is by no means strange that the facts referred to (the amount of subject included on the plate), should be omitted from different systems for calculating exposures. The plain fact is, that this factor, as regards any influence upon the time of exposure, has no existence outside Mr. Michael's imagination.

In the first place, look at the question from a practical point of view. I carry with my 7½ × 5 camera, four lenses, of 7½, 9, 10, and 12 inches focus. I have often taken photographs from the same point of view, with the 7½ and 12 inch lenses within a few minutes of each other, giving the same exposure with apertures which have the same ratio to the focus (*f*-22 for instance). In no case have I found that the wide angle picture had received a greater exposure than the other. I think most practical photographers will bear me out in saying that we may safely accept the opticians' statement that, for all practical purposes, the statement of the ratio of aperture to focus, gives all the needful information regarding the rapidity of a lens.

Even the absorbing and reflecting capacity of the glass has, I think, less influence than some think, and I have failed to discover that a single lens with, say, an aperture of *f*-16, requires less exposure than a doublet lens with *f*-16. A few months ago I made some definite experiments in this direction.

I set up a white reflecting screen in a room illuminated by steady sky light. I fixed a camera at such a distance that the widest angle lens would not include more subject than the white screen. I then exposed four plates with four different lenses, each for three seconds with *f*-16 (as marked by the opticians), taking care that each lens was worked at its correct focus. I afterwards measured the opacity of each negative with Captain Abney's photometer, and give the results.

Lens.	Focus.	Aperture.	Opacity of Negative.
Wray Single	10 inch	*f*-16	7
Beck Rectilinear	9	*f*-16	7¾
Taylor Doublet	5	*f*-16	7¾
Ross Portrait	3½	*f*-16	7½

The negatives were developed in the same dish, with the same developer, for the same period of time.

I was afterwards curious to compare the exposure given by a simple aperture (no lens) with that of a lens. I therefore exposed a half inch diaphragm at eight inches (*f*-16) for six seconds, and directly afterwards a Beck Rectilinear at *f*-16, under similar circumstances as before, and carefully measured the opacities of negatives. They were: simple aperture, thirty-six; and Beck lens thirty-five, practically identical. To return to the original subject. The fallacy of Mr. Michael's argument is, in assuming that a large amount of subject will transmit more light to the plate than a small amount. Neither theory nor practice supports this.—I am, yours, &c., ALFRED WATKINS.

Hereford, May 28.

STAINS ON PRINTING-OUT PAPER.

To the EDITOR.

SIR,—With reference to the letter of the Britannia Works Company in your last Friday's paper on the above subject, I may say, first, that it is a mistake to suppose that I complained about the prints toning slowly, as the first lot toned so quickly that I could not tone more than three at a time without over-toning; even the last lots have toned twice as quick as ordinary sensitised paper. What I complained about was the poor tone, and the stains in all but the first lot, although I used my usual toner—eighty grains borax and one grain gold—until advised to use more by the Britannia Works Company. I always use fresh solution each time; secondly, I must admit that my monogram on the paper I sent was not as plain as might have been, therefore I think there is no necessity for the Company to apologise to me for not being able to read it; thirdly, the pieces of paper referred to in my last letter have arrived, and are free from stain, and the tone is good; fourthly, it may be ignorance on my part, but I must say I do not agree with the Company that the stains are caused from want of gold, or why should not the marks be all over the paper; and why do they come in the printing before they have been near the toner?

I think, instead of the Britannia Works Company apologising to me for not being able to read my monogram, it is my place to apologise to the Company for not having acknowledged the receipt of the prints in your paper of Friday last.—I am, yours, &c., W. ALFRED MEIOH.

Ash Hall, Stoke-upon-Trent, May 30, 1892.

BROWN TONES ON OPALS.

To the EDITOR.

SIR,—For some years I have been invariably successful in making gelatino-bromide emulsion for coating opals, giving very pure black tones. I have recently made three lots, and each one gives me a *warm sepia* tone. The chemicals are Johnson & Sons, carefully weighed; the gelatines, Nelson's No. 1 and Heinrich's. Can you, sir, give me the cause of the brown colour, and how to avoid it? If you could briefly give me a good formula, I should be obliged. There is nothing on the subject in the last five or six ALMANACS. The gelatines have been kept in a dry cupboard since October, so I cannot suppose that any deterioration has taken place, and the ammonia bromide, ammonia iodide, and ammonia chloride are from the same stock I used successfully in the winter. I used ferrous oxalate developer, and no matter how much under or over exposed, I can get no other colour than brown. The pictures I now get are fine enough, but I am altogether puzzled with the remarkable change of tone.—I am, yours, &c., H. BARRY.

Bridge-street, Chester, May 21, 1892.

REMOVING SILVER STAINS.

To the EDITOR.

SIR,—In your last issue you ask for experiences with an American formula for removing silver stains. About a week previous I had seen the same formula in G. Mason & Co's *Photographic Guide*, accredited to Daniel Robertson. Having by me a negative which had been silver stained two or three days before, I tested the process. Immersion for from five to fifteen minutes was said to be sufficient. I found that thirty minutes in two freshly made baths failed to remove the stain. No apparent reduction in the image took place, nor was the silver in the stain removed, but the objectionable red colour was gone, as also the yellow stains from pyro development. The negative now resembles one produced by eikonogen. It would appear to be hopeless to expect any agent to remove the light reduced silver of the stain without attacking the developed image.—I am, yours, &c., J. MCINTOSH.

14, *Lowman-road, Holloway, May* 24, 1892.

Exchange Column.

*** *No charge is made for inserting Exchanges of Apparatus in this column; but none will be inserted unless the article wanted is definitely stated. Those who specify their requirements as "anything useful" will therefore understand the reason of their non-appearance.*

Will exchange three showcases, two feet by three feet, for 8×8 backgrounds or accessories.—Address, H. E. WATKIN, Grand Studio, Marine Parade, Scarborough.

Wanted to exchange THE BRITISH JOURNAL OF PHOTOGRAPHY for 1890 and 1891, for a quarter or half-plate rapid rectilinear lens.—Address, E. BALLEY, 44, Lime-grove, Bideford.

Whole-plate portrait lens, by Shepphord, will exchange for rectilinear or cabinet also print-washing apparatus, exchange studio accessories.—Address, S. J. GANNON, Chelmsford.

Lancaster's quarter-plate Instantograph and three dark slides, also a hand camera to carry twelve 3¼×2¼ plates, in exchange for a half-plate camera, or a good quarter-plate hand camera.—Address, F. HOLWILL, 44, Lime-grove, Bideford.

Answers to Correspondents.

All matters for the text portion of this JOURNAL, *including queries for "Answers" and "Exchanges," must be addressed to* "THE EDITOR," *2, York-street, Covent Garden, London. Inattention to this ensures delay. No notice taken of communications unless name and address of writer are given.*

**** Communications relating to Advertisements and general business affairs must be addressed to* "HENRY GREENWOOD & Co.," *2, York-street, Covent Garden, London.*

E. BARBEN.—A distinct trace of iron in the water would doubtless produce such a stain.

B. J.—Both formulæ are published by the Company. Probably you had better employ the later one issued.

E. A. CARNELL.—No photographic exhibition to be held at the Crystal Palace this year that we are aware of.

W. COX.—Probably a trace of iron was left in the prints, notwithstanding the careful manner in which you appear to have cleared them.

G. G. BAGSTER. We should be pleased to receive the communication. We described the result of M. Lippmann's latest experiments a few weeks ago.

R. WALTON.—From the fact that a very large number of plates are daily sent abroad, it may be fairly assumed that they are fully appreciated by some foreigners at least.

BECCLES.—If all the plates turned out well with the exception of those you changed in that particular dark room, it would seem to indicate that the light was at fault. The light in hotel dark rooms, as we have said on former occasions, is not always to be relied upon.

C. WHITEHOUSE.—The pier companies and the proprietors of gardens and parks can, of course, lay down their own conditions as regards taking photographs on their property. But in the case of piers it is petty to extract heavy fees, if, indeed, it is not a mistaken policy, as few persons will pay them.

R. A. BROOME asks where china plaques for vitrified photographs are to be obtained.—We believe they may be had from most of the Staffordshire china manufacturers. Mintons and Brownfields, we think, both supply them, and they have London offices, which will be found from the Directory. Mortlocks, if we mistake not, also supply them.

W. A. J.—If the paper turns brown a few hours after being sensitised, while two other samples floated on the same bath keep good for two or three days, it shows that there must be something wrong with the paper. The addition of nitric acid to the solution might improve matters, but then it would probably not work well with other papers.

A. C. C. has been essaying the wet-collodion process, and sends us a negative for our opinion, as he has not a negative by that process with which to compare his work.—The negative is a very poor specimen indeed. It is fogged and streaked, as well as slightly stained in development. The bath is out of order; try the effect of an addition of one or two drops of nitric acid.

F. THOMAS says: "When enlarging, it makes my eyes go very red all about them, and I attribute it to the red or ruby-coloured glass, which seems to have a strain on one's eyes. What would prevent this? Would using blue spectacles in the enlarging room prevent it (the strain on the eyes), or what do you recommend?"—Probably a shade would be a sufficient protection.

S. Y. complains that he has taken a dozen cabinet prints from different batches, and cut them in half. One-half he has mounted on cards recently received. At the end of a month the mounted halves show spots, while those kept unmounted are quite perfect. He wants our opinion.—It is this: It is clear that the evil is due either to the cards or the mountant. We cannot say which.

MESSRS. MCGHIE & Co., of Glasgow, write: "We notice, in answer to a correspondent, you state that 'Monckhoven's tissues or films are not obtainable.' We would respectfully inform you that we have a large stock of the different colours, and the demand for this class of paper is increasing. The same remarks apply to a query you answered some time ago regarding photo-mechanical papers."

BEGINNER.—The fault in the prints is that the negatives are much under exposed. The professional who made the print is quite correct when he says it is impossible to get better prints from such negatives. You say the shutter you use is the best and quickest that is made. Quite so, and probably that is the cause of the trouble. It has been set to work too quickly for the plates. It is easy to obtain rapid working shutters but not so easy to obtain plates sufficiently sensitive to respond to them, particularly when used by a novice.

VICTIM says: "About a fortnight ago I sent my photograph (cabinet size) to a firm, in answer to an advertisement for an assistant, and they have not returned it. I wrote to them last week and asked them to return it, and they sent reply to say they thought they had returned it, but if they find it laying about they will send it to me. That seems to me rather unbusinesslike. Is it a firm that is on your black list? I have enclosed the name and address of the firm mentioned, and also my own, but not for publication."—The firm named is, we believe, a respectable one.

C. A. S. asks, I, if the owner of a racing yacht can prevent any one from taking a photograph of it when the vessel is in the open sea. 2. Now, yachts are photographed in full sail when competing at regattas. Whether are they taken with long-focus lenses from the shore or from another boat?—In reply: 1. No; certainly not. 2. The way yachts are usually photographed is this: The camera is on board of another vessel, usually a steam tug or a steam launch, the vessel steaming in the same direction, and at about the same speed, as the yacht is going. It is by this means that the sharpest yacht pictures have been obtained.

C. MARTIN says: "I have just purchased an old lens of Voigtlander's make, about the half-plate size. On the inner tube there is an engraved scale, the divisions being about the sixteenth of an inch or a little more. Can you tell me what is the use of it? I have not yet tried the lens, as I have not a camera to take it."—Apparently the lens is a very old one, and the visual and chemical foci are not coincident. The divisions on the scale indicate the amount of alteration that is necessary to be made after the image has been focussed in order to obtain a sharp picture.

G. L. says: "Just before Christmas last I sent a negative to a firm to make me one 12×10 enlargement, and finish in oils ('paper'), enclosing postal order for same. About a month after I received the enlargement, but, owing to the likeness having been destroyed, I returned it at once for alteration, and, in reply, received a request to send the negative again, as they could do nothing to improve the likeness, and therefore wanted to make another enlargement. Up till now I have neither received enlargement nor can I get any answer to repeated letters asking for an explanation, and my clients now say they will not take it, as I have disappointed them so often. Can I take any proceedings to recover the amount paid and the loss I shall sustain on the order? I may state the enlargement was not promised for any time, but I think four months quite sufficient."—To ensure the return of the negative, we should recommend you to communicate with the local superintendent of police. As to whether you could recover damages for the non-delivery of the enlargement, a solicitor's opinion would be your best means of ascertaining.

RECEIVED.—W. J. Stillman, Albert Levy, Mortimer Field, and W. Borough. In our next.

NORTH LONDON PHOTOGRAPHIC SOCIETY.—Tuesday, June 7, *Retouching*, by Mr. Redmond Barrett, at 8.15 p.m. Visitors are invited.

LONDON AND PROVINCIAL PHOTOGRAPHIC ASSOCIATION.—June 9, Members' Open Night, 16, *Some Prime Factors in Exposing*, Mr. Howard Farmer. 23, Annual General Meeting.

NEWCASTLE-ON-TYNE AND NORTHERN COUNTIES' PHOTOGRAPHIC ASSOCIATION.—Joint Outdoor Meeting, Newcastle Photographic Association and Hexham Photographic Society, to Stocksfield on June 16. Train leaves Central Station, Newcastle, at 9.60 a.m. Leader, Mr. J. P. Gibson.

PHOTOGRAPHIC CLUB.—June 8, *Dodging Negatives for Printing.* 15, *Platinum Possibilities.* Bank Holiday outing next Monday to Gomshall and Shere. Train from Charing-cross at twenty-eight minutes past nine; London Bridge, thirty-five minutes past nine. Train does not stop at Cannon-street.

STOP THIEF!—The Eastman Company write us that a No. 4 registered Kodak, numbered 7806, was, on the 31st May, 1892, stolen from the counter in their shop. They ask our assistance in the hope that the camera may be offered to one of our readers, who would no doubt be willing to help them in the detection of the thief.

MESSRS. J. LANCASTER & SON'S 1892 catalogue should be invaluable to amateurs, as it includes particulars of the firm's innumerable productions in the way of apparatus and sundries for the prosecution of the popular art. It may, indeed, be truly said that both rich and poor will find in these handsome and well-illustrated pages every opportunity for satisfying their requirements. The amateur who is without Lancaster's catalogue cannot claim to be up to date.

MARION'S PHOTOGRAPHIC PASTE.—Messrs. Marion & Co. have sent us a bottle of a new paste introduced by them for mounting prints. Its nature and uses will be amply ascertained from the label, which instructs us to "lay the print to be mounted face downwards on a clean surface, and paste evenly with a hog-bristle or indiarubber brush. When thoroughly spread, place the print on the mount and press well down with a pad of clean blotting-paper, pressing out all air bubbles."

CHICAGO EXHIBITION, 1893.—The Royal Commission have appointed a Photographic Committee, consisting of Captain Abney, Francis Cobb, James Dredge, G. Davison, Colonel J. Gale, H. P. Robinson, and Sir Henry Trueman Wood, to form a collection of photographs representative of the best work which is now being done in this country, both by amateurs and professionals, for the photographic department of the Chicago Exhibition. The pictures lent for this purpose will be transmitted to Chicago and brought back thence free of charge to the exhibitors, and the Royal Commission will also undertake their care while they are in the exhibition. The Committee propose to send an invitation to a limited number of photographic artists, and hope to be able to get together a collection which will be worthy of the present advanced condition of photographic art in England. Pictures will only be received from those to whom invitations have been addressed. In addition to this selected collection, there will be many photographs sent by exhibitors at their own cost, and for these space will be allotted in the usual way.

**** Several contributions and answers to correspondents are unavoidably held over.*

JOURNAL OF PHOTOGRAPHY.

No. 1675. Vol. XXXIX.—JUNE 10, 1892.

THE FIXATION OF SILVER PRINTS.

The question raised before the London and Provincial Photographic Association as to the possibility of testing otherwise than by ocular observation whether a print is sufficiently fixed or not is one of the very highest importance, more especially where large numbers are manipulated at one time. In dealing with a small number, it is perfectly easy, by employing a sufficiency of solution, and moving them about for a given time, so that the bath has free action upon each, to ensure that all are thoroughly cleared of all unreduced silver chloride and albumenate; but when very large numbers are worked at once, as in professional establishments, it is not so easy to give to each one the same individual care. Not only is there a tendency to curtail the quantity of solution used, but the very fact of their numbers precludes the possibility of turning them over so thoroughly or of preventing their massing together so as to cause irregular action of the hypo.

This is a prolific cause of imperfect or irregular fixation, and, while an obvious remedy exists in increasing the bulk of the solution and exercising care that each individual print is submitted to the full action of the bath for a proper time, no practical test appears to be available of the thoroughness of the treatment; and, if such did exist, it would have to be applied to each single print, with the result that those that were not completely fixed would be spoilt at once, instead of remaining to fade with more or less rapidity. The plan adopted in many large establishments of employing two separate baths, and removing the prints one by one from bath to bath, seems the most likely method of ensuring the perfect action of the solution; but this necessarily involves time, and is therefore liable to be shirked by the apprentice or assistant to whom such work is usually relegated.

We have said that no test appears to be available, because it is obvious that a print freshly removed from the hypo bath must contain a certain proportion of silver compounds in the soluble condition, although it may be perfectly fixed, that is to say, may have had all the silver chloride and albumenate dissolved. Consequently, before such a print can be tested for insoluble compounds, it must be freed by perfect washing from all the soluble decomposition products of the operation of fixing. And here we may point out that some misapprehension seems to exist as to the terms "imperfect fixation" and "imperfect washing." The original question put by the examiner may have *meant* either one or the other, but the members of the London and Provincial Association were undoubtedly correct in reading it in its literal sense as referring to the action of the fixing bath alone.

A print may be turned out in three separate states. It may be imperfectly fixed but perfectly washed; or, *vice versâ*, thoroughly fixed but insufficiently washed; or, again, neither operation may have been thoroughly performed. In the first instance, it will contain insoluble silver chloride and the practically insoluble sodio-silver hyposulphite; in the second instance, it will contain soluble hyposulphite of silver and soda, together with chloride of sodium and hyposulphite of soda; while, in the third case, it will contain the whole of these materials, both soluble and insoluble. Obviously, each class of print will require different treatment in testing, and in the case of the perfectly fixed print alone can any really efficient test be applied. Starting with the understanding that the whole of the unreduced silver compounds, chloride and albumenate, have been brought to the soluble condition by the full and free action of a sufficiently strong hypo solution—which means that they have been converted by the hypo into the soluble form of sodio-silver hyposulphite ($Na^4Ag^2S^6O^9$), together with chloride of sodium—all that is required for their removal is plentiful washing in repeated changes of water, and a suitable test applied to the washing water will indicate when the whole of the hyposulphites have been eliminated. Of these tests there are many of greater or less delicacy, and the one test will apply to the full batch of prints.

But when, from the use of too weak a solution, too short an immersion, or the adhesion together of the prints in the dish, the prints are insufficiently fixed, the most perfect washing possible will leave behind the insoluble double hyposulphite of soda and silver ($NaAgS^2O^3$), together with, in all probability, unacted-upon silver chloride and albumenate. No test applied to the washing water is of the slightest value under such conditions, as the impurities remain in the prints themselves to which the tests must be applied, with the result, already mentioned, that they are at once spoiled by the formation of sulphide of silver, itself unremovable by any known agent that will not destroy the paper.

In the case of a large batch of prints, then, that it is desirable to test for sufficiency of fixation, the only practical plan appears to be to select a single print hap-hazard and submit it to the test for silver and hyposulphites, and, if it be found wanting, to pass the remainder of the batch through a freshly made bath of hypo, when, if ordinary care be applied, it is difficult to imagine that they can be anything but thoroughly cleared, and a thorough washing will place them in a condition of safety. The original carelessness, then, involves merely the loss of a single print and the expenditure of a little more time and material. It must be observed that no test is applicable until the prints have been thoroughly washed; or, rather, that the test for thorough washing must be satisfactorily answered before that for fixation is of any use, because, so long as any soluble hyposulphites remain, they will respond equally with the insoluble.

The next question that arises is as to the test to be applied.

Mr. Lyonel Clark in his article mentions potassium bichromate, which he states is employed for testing whether paper is sufficiently sensitised—an application, we may remark *en passant*, we have not previously heard of, and the value of which seems dubious. Its use for the purpose under discussion is, however, perfectly valueless, as was mentioned at the meeting of the London and Provincial Photographic Association, since a print *that had not been fixed at all*, if thoroughly freed by washing of its soluble silver nitrate, would fail to give any reaction with the chromate. It is possible that it might react with the insoluble double hyposulphite of soda and silver, if that were present in a print; but, even granting that, the silver chloride would be beyond the test, and might be present alone.

The alkaline sulphides also mentioned by Mr. Clark are undoubtedly efficient for the purpose, forming most delicate tests for silver either in the soluble or insoluble form; but, as Mr. Clark suggests, these reagents would most probably be *too* delicate, and, by acting upon the image itself, especially in its more delicate portions, give a false character to the print tested. On the whole, therefore, we should incline to reject that method of testing.

The double hyposulphite of soda and silver is, however, very soluble in various reagents, including hypo itself, ammonia and other alkalis forming extremely sweet solutions, as any one may prove by letting a drop from a newly fixed print fall on the tongue. These solutions, if tested with a soluble chloride, give a silver reaction, owing to the superior solvent power of the substances named, especially hypo, but, if in a sufficiently concentrated condition, iodine or a soluble iodide, will form a precipitate, owing to the lower degree of solubility of the iodide of silver. A suspected print might, therefore, be boiled or digested in a small quantity of water containing a little ammonia, and the solution tested with iodine, or a drop of ammonia or solution of soda or potash be dropped on the print, and afterwards a drop of solution of iodide of potassium, when a yellow stain of iodide of silver would be formed. This method would perhaps be scarcely delicate enough in most cases, so an alkaline sulphide dropped into the solution, in which the print had been digested, would give a precipitate of sulphide of silver, an indication that would be free from the objection raised against its application to the print itself.

In very bad cases, or where it is suspected that the prints have adhered together in the fixing bath, simple immersion in a solution of iodide of potassium would betray the presence of any considerable quantity of either chloride or insoluble double hyposulphite of silver by converting them into silver iodide, easily recognisable by its yellow colour; and this plan possesses the advantage that it would have no ill effect on the print, since the iodide of silver could be easily removed by reimmersion in a fresh bath of hypo. In this it would seem we have a practical test, to which the whole of a suspected batch of prints might be submitted without injury, though the indication in slight cases would be perhaps very faint.

Alum solution forms another fairly delicate test, though it produces a permanent precipitate of silver sulphide, and is therefore only applicable to a selected print. Its action is to decompose the hypo and precipitate the silver in the form of sulphide, while further indications of the presence of the hyposulphites are given by the odour of sulphuretted hydrogen and sulphurous acid given off.

Finally, the hyposulphites of silver, both soluble and insoluble, are readily decomposed by heat and converted into sulphide. Hence, dipping a suspected print into boiling water or heating it in a weak alkaline lye would, by the production of the characteristic brown discolouration, reveal the presence of the enemy.

These seem to be the most feasible methods of testing the fixation of prints, and, if they are not as effective as could be wished, perhaps some benefit may accrue from a recognition of the difference we have pointed out between imperfect fixation and insufficient washing.

YELLOW SCREENS FOR ORTHOCHROMATIC WORK.

It is obvious that the employment of the yellow screen in orthochromatic photography opens up at the outset the question as to the choice of a tint for particular classes of work, so that in the resulting negatives the relative colour values of the subjects are rendered with uniform accuracy. For instance, a subject, rich in bright blues and very subdued yellows and greens, might require a screen rather deeply stained, in order, while effectually cutting off the blues, to allow the other colours to assert themselves sufficiently in forming the image. Reversing those conditions, however, the necessity of employing a deeply-tinted screen disappears, and hence a light screen might be used, to the advantage, of course, of considerably shortening the exposure.

The foregoing examples tend to show that, where a photographer engages in orthochromatic work constantly, the variations in the relative and particular colour values of the subjects he has to reproduce require that he should provide himself with a number of screens of different intensities of colouration. Practically, however, we believe that a large number is unnecessary, for a little reflection will show that, say, five differently coloured screens are susceptible by combination, according to the requirements of circumstances, of being so utilised as to constitute a much greater number of screens of varying depth of colouration.

We have been asked this week by a correspondent to give him some idea of the method employed for colouring the pellicular structures used so much abroad as colour screens, and also to inform him of the means he should take for preparing the pellicles of different, and at the same time of regularly increasing, depths of tint; and, as the matter may possibly be of interest to many of our readers, we embody our reply in the form of a short article. We are aware that considerable variety of opinion prevails as to the advantages or disadvantages of the yellow screen with orthochromatic plates, into which controversy, however, we have no present intention of entering.

To the late M. Boissonas, we believe, is due the following plan, which we outline as briefly as possible, of making two solutions provide no less than four screens, increasing in intensity in the order of their enumeration, and equally so prolonging the necessary exposure in a like ratio. Experiment led him to determine that with what he called No. 1, or a faint yellow-coloured screen, the exposure of the orthochromatic plate, which, without a screen, was unit or one, was increased by that screen from $1\frac{1}{2}$ to 3 times, according to the intensity of the light; No. 2, a darker screen, increased it from 3 to 6; No. 3, still darker, from 4 to 9; and No. 4, from 6 to 12. The preparation of the coloured pellicle was conducted as follows:

Four sheets of good glass, of the size thirteen centimetres by eighteen, were coated with a thin film of wax in benzole, applied with a clean fabric, dried over the heat of a spirit lamp, and the surface slightly polished. When quite dry, an edging of benzole was given to the plates, which were then coated with

a plain collodion containing 2 drops of glycerine per 100 c.c. Two solutions were then prepared: No. 1, the colouring solution, consisting of white gelatine, 7½ grammes; glycerine, 1 c.c.; distilled water, 95 c.c.; phenique acid, 2 drops; and 5 c.c. of a half per cent. alcoholic solution of aurantia; solution No. 2 consisting of 7½ grammes of white gelatine, and 1 c.c. of glycerine in 100 c.c. of distilled water. In each case the gelatine was dissolved first and the other substances added afterwards, the two solutions being well filtered and kept at a temperature of 120 F.

For the first or lightest tint 10 c.c. of the colouring solution were mixed with 30 c.c. of solution No. 2, and applied to one of the collodionised plates. The second or darker tint consisted of 20 c.c. each of the two solutions; No. 3, of 30 c.c. of the colouring solution and 10 c.c. of the gelatine solution; and No. 4, simply of 40 c.c. of the colouring solution alone. Thus the depth of colour is in the inverse proportion of the dilution of the colouring solution with the plain gelatine. When the films are perfectly dried, they are each coated with another film of collodion, and finally stripped from their supports.

The films of coloured gelatine so prepared are adaptable for employment in the diaphragm opening of the lens, being secured within small discs for that purpose; equally so they can be applied to optically worked glass, and used in the ordinary way. Collodion alone gives a thinner film than gelatine, and screens of the tints above specified are prepared by dissolving one gramme of aurantia in 100 c.c. of plain collodion for the colouring solution and mixing five c.c. of it with fifteen c.c. of an uncoloured solution, and for the other tints, respectively, ten c.c. of each, fifteen and five c.c. of each, and twenty c.c. only of the coloured collodion solution.

We believe that coloured gelatine and collodion films for orthochromatic work are articles of commerce on the Continent where they are in extensive use; and probably the information as to their preparation here given may be of service to the increasingly large number of people who are taking up orthochromatic work, and find that as much attention has to be given to the properties of the screen as to the plates themselves.

Photo-Technical Education at Home and Abroad.—At the Photographic Society of Great Britain's next meeting on Tuesday, June 14, Mr. E. Howard Farmer will read a paper on this subject, in which he will compare the teaching (and the results of the teaching) in photo-technology which has been given in England with that given on the Continent. As the statement made at a meeting of the Society, "that there was no place in England where photo-instruction could be obtained," has done the Polytechnic School of Photography serious injury, Mr. Farmer is anxious to make the subject of his lecture as public as possible.

Collecting Fine Precipitates.—Some years ago, in renovating by nitrate of baryta an old bath, we took some trouble in collecting and examining the small quantity of precipitate produced by the baryta. From a Winchester solution we obtained a very minute precipitate which was very troublesome to collect. Mr. W. H. Barber, in the *Chemical News*, proposes a very neat way of dealing with such difficulties. He recommends the addition of finely divided asbestos to solutions containing a troublesome precipitate, and the collection of the whole on an asbestos plug. The precipitate may then be washed, redissolved, and estimated with great ease.

Ammonia as a Fixing Agent.—The evanescent character of silver is primarily attributed to the hyposulphite of soda used for fixing, or the hyposulphite compounds formed during the operations and their imperfect removal in the after-washing. Indeed directly, or indirectly, "hypo" is made, and not without cause, the bugbear of fugitive silver prints. Now, it may not be generally known to a great number of modern photographers that ammonia is a very good fixing agent, the unaltered by light chloride of silver being freely soluble in that menstruum. In olden times it was frequently used in that capacity. The unfortunate thing in connexion with ammonia as a fixant is that it cannot be used with albumenised paper, inasmuch as it dissolves the albumen. There is no reason, however, why it should not be employed for plain paper, as by its use no hyposulphites—if they be the cause of fugitiveness—could be formed. Those who are working with plain paper might give it a trial. It need scarcely be remarked that ammonia is by no means an agreeable material to work with; but some might be inclined to overlook that fact if permanence were ensured.

Action of Light on Sulphite of Silver.—In a recent number of the *Chemical News*, Mr. W. H. Sodean relates some experiments with regard to this action of light which have a decided photographic interest. The salt was prepared by passing sulphurous anhydride into a solution of recrystallised nitrate of silver, washing the precipitate thoroughly, and completely desiccating by keeping it in a vacuum over a mixture of sulphuric and chromic acids. When kept in hermetically closed tubes it was slightly blackened after a fortnight's exposure to sunlight. When the temperature was raised the blackening was more intense and more quickly brought about. It was noted also that when moisture was present the darkening was accelerated. This latter effect might be anticipated, for it is well known that many familiar gaseous reactions are absolutely impossible when the gases before mixing and the containing vessels have been rendered perfectly free from water vapour. Quite recently, for example, it has been shown that sulphuretted hydrogen gas, so fatal to silver prints and injurious to silver articles, is quite without action upon silver and other salts when quite dry.

Ordnance Maps.—It will be remembered that in June last a Departmental Committee of the Board of Agriculture was appointed to inquire into various points in connexion with the Ordnance Survey of the United Kingdom and report thereon. That report has recently been presented to Parliament. From it we learn about that 2400 persons are now engaged in the different branches of the survey, a very large proportion of them being the military—the Royal Engineers. The most important work the Office now has on hand is the completion of the twenty-four-inch scale maps. It is interesting to learn from the report, thanks to photography and photo-zincography, that the sale of the maps to the public now pays the expense of publication. This will, no doubt, be surprising to some who have had the opportunity of seeing the work in progress at Southampton, and the time and care expended upon it; and, without this, it would be impossible to produce the excellent results issued. Few commercial houses, we imagine, would find it remunerative to bestow the same amount of time on their work as that expended upon that at Southampton.

Albumen and Sulphur.—The connexion of these two bodies has a close bearing upon the most familiar form of silver print, and Herr Rosing has discovered the singular fact that, when an emulsion of pure sulphur is mixed with egg-albumen, a decomposition takes place. The albumen is oxidised, a hydroxyl group derived from a molecule of water replacing a hydrogen atom in the albumen molecule, whilst the displaced hydrogen atom unites with the remaining hydrogen atom of the water molecule and with an atom of sulphur to form sulphuretted hydrogen. This action, however, does not take place when no water is present, nor when neutral salts capable of combining with water are present, nor when the albumen has been previously with iodine or other substances. Now, it is evident, that in a print in which toning takes place by "sulphurisation," we have conditions very similar to these—albumen and sulphur in a fine state of division brought into close contact, with a probability of the gradual production of sulphuretted hydrogen, its gradual oxidation to sulphuric

acid, and the destruction of the print. The question that arises is, whether the albumen has been previously hydroxylated during the various processes it has passed through.

Chromo-Photography.—The controversy with reference to chromo-photography and Mr. Ives' recent demonstrations does not seem to be confined entirely to the technical press, for Dr. Vogel had a long letter in the *Standard* on the subject of his own investigations and that of others many years ago. Other letters on the subject have also appeared in the lay press from other writers. Now every one in this country is always anxious to give credit to whom credit is due, whatever may be their nationality. There is another phase of the question that appeals to the more practical portion of the public, namely, the commercial value of the results. Mr. Ives has shown photographs in colours on the screen, and described the methods by which they were produced. Dr. Vogel's work lies in a different direction, though on the same basis—that of producing chromo prints by printing from three plates made from three negatives; that is, pictures in all the colours of nature with three printings only. So far as we are aware, none of the Doctor's recent examples have reached this country as yet. But we are informed by a friend who has had the opportunity of seeing them, and who is fully qualified to judge, that they are far and away the best results in this direction he has hitherto seen; and he is quite familiar with the best that have been shown in this country.

Stains on the Margins of Plates.—A question was recently put at one of the metropolitan Societies, as to whether stains at the edges of a plate were to be taken as a proof that the plate was an old one. Any answer to this question ought only be given with a qualification. A plate may be old and yet show no stain, or one may be comparatively new and yet show a marked stain. We recently worked with some plates which the date upon the box showed had not been made a year, yet they had a strong iridescent stain encroaching well into the plate; while, a short time back, we developed some plates that were nearly seven years old, and they showed practically no stain whatever. These plates were packed in contact with each other, with a piece of paper between slightly smaller than the glass. The only trace of staining was where the paper did not cover the film, and so protect it from the atmosphere. The other plates alluded to were packed in the general way with slips of paper—unusually thick—separating them, so that the films were exposed to the air and noxious vapours it contained, also to any deleterious exhalations from the packing paper. From this it will be seen that the presence or absence of marginal stains cannot be taken as any criterion as to the age of a plate. Again, the keeping qualities of plates coated with emulsion made by the boiling and by the ammonia methods vary considerably.

Photography Abroad.—A question is often asked in professional circles, when the effect of amateurs on the business is the subject of conversation, as to whether amateur photography has assumed the proportions on the Continent that it has done in this country. If the number of photographic societies can be taken as any criterion, it certainly has not; for it must be borne in mind that it is of the amateur elements that the larger proportion of them are composed. At the present time there is scarcely a large village without a society, and most towns of importance have several. Upwards of 250 photographic societies at present exist in the United Kingdom. It is very doubtful if all the societies throughout the world were added together they would amount to anything like this figure. Many very large and important cities on the Continent have no photographic society whatever, yet they contain, proportionately, as many, and in some instances more, professional photographers than places of corresponding size here. Munich, for example, with a population of between 300,000 and 400,000, and a very large proportion of professional photographers, as well as numerous large photo-mechanical establishments, possesses but one photographic society, and that numbers fewer members than the majority of the societies in the suburbs of London or small country towns.

Old Portrait Negatives.—What shall be done with old portrait negatives? Those who do a large portrait business find themselves, after a few years, encumbered with thousands of negatives from which copies will never be required. Photographers, or at least, the higher class ones, tacitly undertake to keep their negatives indefinitely. But some, after the lapse of from seven to ten years, set no further value upon them; yet there is an old saying amongst the profession that, if a negative be destroyed, copies from it are almost sure to be required. At one time, in the old collodion days, it was worth while to clean off old negatives—particularly when patent plate was employed—to use the glass again. Now, "that game is not worth the candle," because glass is so very cheap. What, then, shall be done with the stock of old and valueless negatives? Mr. Silvy, and others, when they retired from business, advertised that their old sitters could purchase their negatives for a small sum, and many were disposed of in this way. But some who tried the same plan some few years ago met with but little response, doubtless because but small value—now that people sit so frequently—is set on portraits after they are a few years old. This fact should be kept in mind by those purchasing businesses. One thing is certain, namely, the negative of a portrait should never go out of the hands of the photographer unless to the sitter.

An Astronomical Detective on Duty.—The interest of the paper recently read at the Parent Society's meeting upon the use of photography in detecting falsifications of documents, cheques, and similar objects that can be closely inspected, sinks almost into insignificance when compared with the latest efforts in searching for the unknown by photographic means. One of the triumphs of mathematical astronomy was the prediction of the existence of a planet owing to the perturbations of certain of the heavenly bodies, and the ultimate discovery of the planet. In a paper read before the Royal Society of Edinburgh in 1880, Professor Forbes predicted, with much confidence, that one or two planets must exist beyond Neptune. He said that there could be no doubt but that two planets moved in orbits external to Neptune, one at about 100 times and one at about 300 times the distance of the earth from the sun. Mr. Isaac Roberts wrote to the Professor for some indications, who replied that within a certain named range the planet, if existent, should be found. A chart of the region was made at Crowborough, and the region was covered by eighteen photographic plates. There was little fear of the object disappearing between successive exposures, for Professor Forbes estimated that before the path it travelled over covered as much space as the moon's diameter the average span of a human life would be twice passed. Two photographs were taken at an interval of not less than seven days, and with not less than an hour and a half exposure. The whole of the plates covering the region were carefully examined, and Mr. Roberts said it only remained for him to report (he was addressing a meeting of the Royal Astronomical Society) that no planets of greater brightness than a star of the fifteenth magnitude existed in the area indicated, nor was there anything in the plates of an abnormal appearance to which it was necessary to call attention. It could be wished that there had been another ending to the investigation, so great would have been the credit that redounded to our science.

OBSOLETE PROCESSES.

No. 3.—Wax Paper.

In the article on the calotype process it was mentioned that it yielded most excellent results. Such was the case, but its practice was attended with some inconveniences, one of the principal being that the paper had to be exposed and developed within a few days, at most, from the time it was sensitised. Indeed, in hot weather, or under adverse atmospheric conditions, it would not keep more than a day, or, if prepared with the maximum of sensitiveness, not beyond an hour or two. This led to the introduction of what was named the "wax-paper process."

In this process the paper, in the first instance, was saturated with beeswax, and, instead of being sensitised with gallo-nitrate of silver,

it was excited with a plain solution of nitrate of silver, strongly acidified with acetic acid. The paper, thus prepared, was, however, much slower than the calotype paper, but it possessed the compensating advantage that it would keep good for weeks, and, under favourable conditions, for months, before exposure. Hence for general landscape-work it superseded the older process. The English paper that was usually considered the best for calotype did not prove so good for the process now under consideration, inasmuch as the sizing matter being gelatine rendered the paper too hard and non-absorbent to permit of its even permeation by the wax with which it had to be saturated. If English papers were, however, employed—as they were by some—they were usually treated with hot water, sometimes slightly acidified, in order to remove some of the sizing matter prior to the waxing. The foreign papers, which were mostly sized with starch, such as those of Canson or Lacroix, were those generally preferred. There were two kinds of these papers, the thick and the thin. It was the latter that was commonly used for negatives.

For waxing the purest white beeswax obtainable was employed. The operation was as follows:—If only a few sheets were prepared at a time, they were laid separately upon a heated iron plate, and a lump of the wax rubbed over them, until the paper became saturated. But the more convenient way—as this paper would keep indefinitely—was to prepare a good stock at a time. In this case the wax was melted in a flat dish, and the sheets floated upon it. When either of the papers just named was employed, they were quickly permeated by the molten wax. The paper was then removed, drained, and the wax allowed to congeal. When a good number of sheets had been thus treated they were each placed between sheets of clean blotting-paper and then ironed with a laundry iron, sufficiently hot to thoroughly melt the wax and cause the superfluity to be absorbed by the bibulous paper. When finished the paper was quite translucent, and had, if properly manipulated, a perfectly even texture.

As the wax, to some extent, prevented the silver salts from combining with the paper itself, it was found desirable to introduce some organic matter with the iodising material, such as sugar of milk, honey, isinglass, albumen, gum, &c. In this matter almost every worker had his own pet formula, as well as for the salts of silver to be formed in the paper, such as the iodide, bromide, chloride, cyanide, fluoride, &c.

Here is a typical formula, and one that gave excellent results:—Distilled water, or, preferably, water in which rice had been boiled, one pint; iodide of potassium, half an ounce; bromide of potassium, ten grains; cyanide of potassium, twelve grains; fluoride of potassium, four grains; sugar of milk, half an ounce; albumen, a similar quantity, and sufficient iodine to give the solution a deep shiny colour. Sometimes, in addition to these materials, others were added. For example, chloride of sodium, honey, isinglass, gum, and several other materials had their advocates. Indeed, it may be almost said that the more complex the iodising solution was the better it seemed to be appreciated by some people. It must be mentioned, however, that there were distinct advantages to be gained by the employment of some of the substances used. For instance, organic matter, like sugar of milk, &c., was indispensable, for the reason already indicated. The bromide certainly enhanced the sensitiveness, and the chloride and the fluoride was, by some, thought to do the same. Again, the cyanide served a good purpose in assisting the permeation of the paper by, in a measure, destroying the greasy and repellent nature of the wax. The iodine, too, was decidedly an advantage in ameliorating, or removing, metallic particles, and furthermore, by combining with the starch in the paper, rendering it a dark blue or violet colour. When so tinted, air-bubbles, or inequalities in the salting of the paper, were at once manifest. The sheets were iodised by immersing them in the solution, where they were allowed to soak for an hour or two, or until they had assumed an even violet tint. They were then hung up by one corner to dry. It was customary to iodise a good stock at a time, as the paper would keep for a long period if preserved dry.

The sensitising solution was thirty grains of nitrate of silver and forty minims of glacial acetic acid to the ounce of distilled water. These proportions were, however, often varied according to circumstances. For example, if the paper were for immediate use, the nitrate of silver might be increased, while the acid was diminished, with a corresponding gain in sensitiveness. Conversely, if the paper had to be kept for a long period before use, the silver was decreased, while, at the same time, the sensitiveness was retarded, good keeping qualities and high sensibility being inimical. The solution could be applied either with a glass rod or by pouring some on a glass plate and floating the paper upon it as described for the calotype process. But, if many sheets had to be sensitised at a time, the solution was generally put into a shallow dish and the paper floated upon its surface. The paper was allowed to remain on the solution until the blue tint of the iodide of starch was discharged. It was then washed in two or three changes of water. The more perfect the washing, the longer the paper would keep, with some sacrifice of sensibility, however.

The exposure, as before mentioned, was much longer than with calotype. But with a portrait lens and a good light out of doors, under favourable conditions, a negative could be obtained in thirty or forty seconds. With a landscape lens, aperture about *f*-30, and paper of medium sensitiveness, an exposure of from twenty minutes to three-quarters of an hour, according to the subject and the quality of the light, was required. Although the paper would keep for some time, it was customary to develop as soon after exposure as possible.

The developer was a saturated solution of gallic acid in water, to which a few drops of the sensitising solution had been added. The paper was floated upon the solution, or sometimes immersed in it. If the paper were prepared for immediate use, it was usually but slightly washed. Then the addition of the silver was not made until the image was well out, the paper having sufficient free silver in it to start the development.

The development of wax-paper negatives was a somewhat tedious operation. If the negative was very fully exposed, the development could be completed in ten to twenty minutes, but, more often than not, it was a question of two or three hours, though, of course, several negatives, in separate dishes, could be developing at the same time. The time was, however, often shortened—frequently with advantage to the picture—by slightly warming the solution. In place of gallic acid, pyrogallic, in the proportion of a grain or two to the ounce of water, was sometimes used. When the image was fully developed, it was well washed in several changes of water, and the surface gently rubbed with a tuft of cotton wool or a broad camel's-hair brush. Extreme cleanliness, it may be mentioned, in working was essential in order to avoid stains and marble-like markings.

The great reformer of the complexity involved in the preparation of wax paper was Mr. F. Townsend, who, with one blow, demolished the great variety of ingredients mentioned in the typical formula given above, and reduced them to two only, iodide and bromide of potassium, with which had been dissolved enough iodine to impart a sherry colour to the water forming the solvent. The advantages claimed for this paper, when excited in a bath varying from fifteen to thirty grains in strength, were great delicacy and brilliance, good half-tones, sensitiveness, non-solarisation, sensitiveness to the green rays, and absolute certainty. We here give Townsend's formulæ, as it is not improbable that some may be induced to try it. At any rate, some negatives of large size, at present in our office, have been seen and examined by many, who declare that they possess features of excellence so great, that upon any details of practice being published they will certainly give the process a trial. The paper is immersed in—

Iodide of potassium	600 grains.
Bromide „	200 „
Water	40 ounces.

To this add four or six grains of iodine, or enough to impart a sherry colour. Let the paper remain immersed in this for two hours. When quite dry, sensitise for six or eight minutes in a thirty-grain silver bath, to which a minim of acetic acid is added for each grain of silver. If the paper is to be kept long, the proportion of acetic acid should be increased. When sensitised, remove the superfluous silver by clean blotting-paper. The development is effected by a saturated solution of gallic acid, to every four ounces of which a drachm of the silver-bath solution is added, together with a few drops of acetic acid (glacial).

The negatives are fixed in a solution of hyposulphite of soda, two ounces to the pint. In this solution they remain until the yellow iodide of silver is completely removed. A thorough washing completes the picture. Generally, when the negatives are dry, they

have a more or less dull or opalescent appearance; but the transparency of the paper is quickly restored by holding them before the fire for a few minutes.

The wax-paper was an excellent process, and one which, in skilled hands, yielded charming results. Many of our oldest readers will call vividly to mind the admirable Russian views that were taken by the late Mr. Roger Fenton in the early fifties.

CONTINENTAL NOTES AND NEWS.

The Paris Photographic Apparatus Exhibition.—From the list of exhibitors in this Exhibition, given in the June number of *L'Amateur Photographe*, we gather that very few English houses indeed have taken installations for the display of their products, and, on the whole, the international character of the exhibition is not well sustained. French firms appear, however, to give it a very hearty support, which may in some degree account for the coldness with which it has been treated abroad.

"The Originator of Emulsion Printing-out Papers."—According to M. Gravier, who lately discoursed on aristotype and cognate processes before the *Société d'Etudes Photographiques*, the process of printing on emulsion printing-out papers was originally made public by the late Dr. Van Monckhoven in 1862. History, however, attributes the introduction of the process to the late Mr. G. Wharton Simpson in the year 1865; but history and M. Gravier are both wrong. So long ago as 1867 we conclusively proved that the collodio-chloride process was first published by Alexis Gaudin in 1861.

Para-amidophenol Nitrate.—The employment of para-amidophenol chlorhydrate in conjunction with sodium sulphite and potassium carbonate has been found by some workers to induce a retarding action of the developer, due to the formation of potassium chloride, which is said to act as a retainer. To obviate this, Dr. Schüchart, of Gorlitz, recommends the employment of para-amidophenol nitrate, which is freely soluble in water, caustic soda replacing the potassium carbonate as the alkali. It is suggested, however, that the substitution of sodium carbonate for the potassium salt in the original formula would equally prevent retardation of development.

Amidol.—According to Dr. Eder, who details the results of his experiments in the June number of the *Correspondenz*, amidol $\left(C_6H_3\begin{cases}OH\\NH_2\end{cases}\right)2$, with the addition of sodium sulphite, and without alkali, acts as a developer *per se*, and is said to be superior in some respects to ordinary alkaline developers. It is, we believe, the case, although it is not generally known, that a solution of eikonogen alone will develop the image, although very slowly. Possibly the addition of sulphite would, as in the case of amidol, play the part of an accelerator.

Blue Positives for the Lantern.—Mr. Gaston Henri Niewenglowoski quite truly says that blue lantern slides may be made by dissolving out the silver bromide from a gelatine plate, sensitising the remaining film with potassium ferridcyanide and ammonia citrate of iron as for blue printing, and exposing, &c., as usual. But the operation appears to us to run the original Chinese idea of how to obtain roast pig very close for circumlocutory indirectness. A simpler plan, possibly, would be to develop an ordinary lantern positive with ferrous oxalate, and before removing the last trace of iron to flood the plate with a solution of potassium ferridcyanide, which would yield the desired azure-tinted picture.

An Imitation Platinotype Paper.—At the April meeting of the Société Française de Photographie, M. A. Pavard read a paper, in which he said that Professor Boivin, after many experiments with the salts of iron, has prepared a paper with those salts as a base, which keeps well, and is cheaper than either platinum or silver paper. It is printed out until the details of the shadows are seen, and, when removed from the frame, the image is either steamed or breathed upon. This developes the picture, which, after washing, is "fixed" in a solution consisting of—

Water		1000 parts.
Hypo		80 ,,
Gold chloride	(1:1000)	20 to 40 c.c.

This bath gives purple, sepia, or warm black tones, according to the length of immersion of the print.

Development and Temperature.—Dr. Miethe has recently been giving some attention to this subject, and remarks that it is well known that in general cold developers act with less energy than warm developers, and that some cold developers give stronger negatives than warm ones. The influence of temperature on the developing power of the various substances varies with different developers. As to the sensitiveness joined to temperature, he places modern developers in the following order: hydroquinone, pyrogallol, iron oxalate, eikonogen. The latter, as regards its reducing power, does not appear to be influenced by the temperature; hydroquinone, however, is so affected that at 40° Fahr. it has no reducing power over the exposed image. Pyro, with a salt of soda, like ferrous oxalate, exhibits little diminished activity even at a point so low as 32° Fahr. At a low temperature, eikonogen gives weak negatives instead of strong ones as do the other developers.

Reversals with Thiosinnamine.—M. H. Fourtier, in the *Photo Gazette*, details the results of some experiments, on the lines of Colonel Waterhouse's now classic work with carbamides in the developer, made in order to obtain reversals in development, in which, however, it appears that he was utterly unsuccessful. Exposing a plate in the printing frame to a positive he obtained a fine negative, with no sign of reversal whatever. It appeared to him that the thiosinnamine played the part of an accelerator, since the image appeared very quickly. This might be accounted for in another way, as it would require a very slow plate and an extremely brief exposure to daylight in a printing frame in order to prevent the image rushing up under development. M. Fourtier also states that a series of instantaneous pictures all gave on development negative results, and the effect of largely increasing the thiosinnamine was to prevent the appearance of any image at all. The thiosinnamine is undoubtedly at fault. Perhaps Colonel Waterhouse would kindly put M. Fourtier in the way of obtaining a suitable sample.

The International Union of Photography.—We have received the rules and regulations of the International Union of Photography, which was founded at the International Congress assembled at Brussels last year. The Union is due to Mr. S. Pector, who conceived the idea of an exhibition which should be a federation of all amateur societies and of all persons interested in photography. "The Society has for its object, in the first place, "the dissemination of ideas, and the making of constant efforts to establish unity of action in regard to photography, so that facilities for the comprehension, study, and utilisation of any new facts might be afforded to all. These facts will henceforth be published in accordance with a method universally adopted, based and expressed on a system generally admitted. The Society also has for its object the collection of information in regard to all fresh discoveries in photography, in the Old and New World, in order to make them universally known to all persons interested in the conquests made by the genius of man over the as yet unknown dominion of the photographic art." The General Secretary's address is, M. Pector, 9, Rue de Lincoln, Paris, and further particulars may be obtained of him.

Printing-out Platinotype.—The following formula, according to one of our Continental exchanges, is simple in working and yields results of the highest class. Suitable paper is floated on a solution consisting of—

Gelatine	6 grammes.
Ammonia alum	2 „
Methylated spirit	120 c.c.
Water	450 „

Float for ten minutes, and when dry sensitise on a mixture of 10 c.c. of each of the following solutions:—

I.

Potassium chloroplatinite	6 grammes.
Distilled water	35 c.c.

II.

Peroxalate of iron	6 grammes 50
Distilled water	35 c.c.

The operations of exposure, development, and clearing are already too familiar to our readers in connexion with the well-known hot-bath platinum process to need recapitulation here.

"**Mixtol.**"—This is the name of a Continental one-solution developer, and the following is its composition:—

Boiling water	1000 c.c.
Sodium sulphite	120 grains.
Hydroquinone	15 „
Eikonogen	10 „
Potassium ferrocyanide	20 „
Potassium carbonate	75 „
Caustic potash	15 „
Potassium bromide	1 „
Glycerine	2 drops.

It would be interesting to persuade the authors of these modern complicated developing and toning and fixing formulæ to state clearly the assumed action which all the various ingredients of the solutions are supposed to have, accompanied with a practical demonstration thereof. The inventor of mixtol, however, has brought his own punishment upon him. He claims that it does not stain the film, and then incautiously advises the use of an acid fixing bath to remove the yellow stain caused in development, with mixtol, of course. He furthermore claims that mixtol keeps well, but only advises its preparation in quantities of from 300 c.c. to 500 c.c. at a time. One of his critics put a finger on the contradictory nature of this piece of advice, and asks why, if the developer keeps well, only a small quantity is recommended to be made at a time; and also why, if it does not stain the plate, an acid fixing bath to remove the yellow stain is recommended?

PICTORIAL SELECTION IN PHOTOGRAPHY.

[Photographic Section of the Croydon Microscopical Society.]

In dealing with the composition of pictures in reference to photography, apart from painting, it is only necessary to treat of: the position and arrangement of lines; the balance of parts; the variation in the tones of light and shade; and the most suitable positions for the introduction of figures or other objects which shall go to form a pleasing picture.

Let me, however, at the outset, explain that it is farthest from my wish to insist exclusively on any one series of rules upon which all pictures should be constructed, any more than I would desire to enforce a standard by which all works should be judged whether they be good or bad. I mean that, having regard to the great difference of opinion held on matters of art, it is useless to lay down an inflexible or hard-and-fast line which admits of no departure. I hope, therefore, the remarks I may make will be accepted rather in the light of "hints," in the carrying out of which a better result may be obtained than would otherwise occur should these points be overlooked or neglected.

Seeing that photography is so purely a mechanical process in which the artist has no chance of leaving out any objectionable object which may detract from the view before his lens, it is of the utmost importance he should know some of the principles on which a good picture is built up, in order that he may in some measure be able to cope with the difficulty and perhaps overcome it. To know where and how to select the best standpoint, how much of the prospect to include in his picture—and, of equal importance, how much he should *ex*-clude—to note the changes under varying lights, the relief of those portions in light against others in shade or cast shadow, the judicious arrangement of parts, or the apt introduction of figures requires more training than the setting up of a camera, the snapping of a shutter, and the subsequent development of a plate; yet it is only on acquiring such knowledge that the photographer is able to excel, or that really artistic pictures can be produced.

To some these matters present little difficulty, they grasp or overcome them without apparent effort, in some instances are hardly conscious of having exercised any discrimination in their choice, and, if questioned on the composition of their pictures, could only tell you "they liked them that way best." Others are not so happy; they never get successful pictures—their horizon is too high or else it is too low, sometimes too dense, at others hard to find; the front elevation of a house appears to afford them interest; whilst a large tree in the centre, with a smaller one equidistant on either side seems, to them, quite an ideal picture, the embodiment of perfection in composition—having a due regard to the equal balance of parts. Sometimes they essay figures or portraits (?) of their friends, and, remembering the triangular form has been, by some, greatly extolled, they straightway place their central figure in a standing position, carefully arranging the residue of their victims in sloping order, on either side, with a result too dreadful to dwell upon.

One could multiply these instances, but enough has been said to show how necessary it is to have either some knowledge of pictorial effect or, failing this, the desirability of becoming acquainted with a few of the rules of art.

Composition is the art of properly disposing or arranging in the most effective manner the various forms and objects which constitute a picture, or, in other words, the judicious selection and combination of various parts which, when united, form one perfect whole. Sir Joshua Reynolds, when speaking of painting, says: "Composition, taken generally, is the principal part of invention, and is by far the greatest difficulty the artist has to encounter. Every man that can paint at all can execute individual parts; but to keep those parts in a due subordination, as relative to a whole, requires a comprehensive view of the art, that more strongly implies genius than perhaps any other quality whatever." Let us now see of what this quality consists; and, in the first place, consider the arrangement of lines.

Lines.

The term "line" is not altogether satisfactory, as there are no actual lines in nature, but it must in this instance be understood to refer to the apparent boundary of different objects, the limit at which they seem to merge the one into the other. The most important line, or that which has the greatest influence on all the others in a picture, is known as the horizon, or "horizontal line," which should always indicate the height of the eye of the spectator. This line varies in height with the position chosen, so that, when standing on a common or the seashore, the horizon appears low, but in ascending a cliff or hill it is found to rise in proportion to the height attained; hence, in the former case of the seashore the horizon would be situated about a third or a fourth of the height of the picture above the base line, whilst in the latter instance it would be much nearer the top. It should not on any account be allowed to divide a picture exactly in the middle, as in this case all lines receding from the spectator, either from above or beneath, would be too equal to form a pleasing result. No exact height need be given, but, as a guide for all open prospects which present great distances at a low level, it would be well to assign the horizon a position not exceeding, say, one-third the height of the picture above the base line, where it would give greater variety to the lines running from the spectator, and altogether form a more pleasing and agreeable composition. For pictures taken from an elevation, the space from base to horizon would perhaps occupy three-quarters of the height of the composition, or possibly even more; but let me here remark that the greatest care should be exercised in determining the height of the horizontal line, as it is on reference to its relative position that an intelligent observer would recognise at once the altitude from which the picture was taken. It is equally necessary to bear this in mind when making "slides" or trimming prints to guard against cutting off more of the foreground than the sky, thereby reducing the height of your horizon, and in consequence falsifying your picture.

Having decided on your horizontal line, it is necessary now to note the direction taken by the other lines, which are regulated by the position of the "point of sight."

Point of Sight.

The point of sight is always situated, as you are aware, opposite the eye on the horizontal line. You will remember the fact that objects are

seen by means of rays of light proceeding in straight lines, some of which meet at the eye of the observer; and I need only point out that, supposing that observer should choose the centre of a long, straight, and level street for the scene of his operations, he would get a series of lines from the ruts, gutters, footways, and houses more suggestive of a geometrical design than a pleasing representation of an inhabited thoroughfare (Fig 1).

Fig. 1.

The same remarks apply to the point of sight as were made in reference to the horizon in the undesirability of giving it a central or middle position. It should be placed, more or less, either to the right or left of the centre, so that, by presenting more of the subject on one side than another, formality is avoided, and the angles of the general lines are more advantageously varied (Fig 2).

Having determined the position of the horizon and the point of sight, it should next be seen how the lines of the landscape compose them.

Fig. 2.

selves. Many methods have been advanced for the most perfect arrangement of lines, but in the infinite variety of subjects which are presented it is almost impossible to be guided by precept alone. Parallel lines should always be avoided, as, apart from their tendency to suggest a geological diagram, they serve to conduct the eye from side to side of the composition, a defect which should be carefully guarded against (Fig. 3). Lines which guide the sight perspectively through the picture, or which lead the eye from the foreground through the middle distance on to the horizon, are always the most pleasing and agreeable, and should invariably be selected in preference to all others (Fig. 4.) Lines which have a tendency to encircle a view should not be lost sight of, as, in addition to the help they afford of keeping the eye in the picture, they also assist to concentrate the attention on the chief point of interest beyond. As instances of this effect I might cite *A Peep between Trees*, or a pathway through a wood, in which the stems and branches of the trees would take the direction named. If in the first position you have chosen to set up your camera you find the lines of the foreground rising perpendicularly from the base line, reject it at once, and move to a spot where they shall incline either to the right or left. The lines, then taking a slanting direction, will lead the eye into the picture

Fig. 3.

in a far more agreeable and satisfactory manner than if they had followed the vertical tendency which obtained in the first situation.

Points.

Observe where the most prominent feature of your landscape comes, whether too much in the centre of your picture or too near its limits.

Fig. 4.

It is generally considered bad taste to have any object coming exactly in the centre of a composition so that it shall be equidistant from the outside lines of the picture, and this should be borne in mind when focussing the landscape, but I shall have something more to say in reference to this later on. Note whether you have one point immediately over another, and, if so, make some little alterations in your position to remedy this defect. Do not have two or more parts of your picture of nearly equal size, neither let the undulations of, say, "a moorland with distant hills" cut up your composition into several equal portions—a circumstance of very frequent occurrence in all such situations as well as in mountainous districts.

W. D. G.

(1) To obtain the distances from the *flange* to the focussing screen, add 3½, 4, and 6 inches for Nos. 1, 2, and 3 respectively.

(2) The angle included is a constant for *one* aperture for any distance of focussing screen, but it diminishes as smaller diaphragms are employed.

The diaphragms are so arranged that for any initial extension (and corresponding intensity) each succeeding smaller diaphragm requires double the exposure of the next larger.

There are seven diaphragms, ranging from full aperture to the *smallest*, which requires sixty-four times the exposure required for full aperture.

The smallest stop reduces the angles included at full aperture in Nos. 1, 2, and 3 to 8½°, 9°, and 6½° respectively.

No. 1 tele-photographic lens consists of the patent stereographic (1·6 inches diameter) in conjunction with a compound negative ⅛ of an inch diameter.

No. 2 tele-photographic lens consists of the 1B. patent portrait (2 inches diameter) in conjunction with a compound negative ⅛ of an inch diameter.

No. 3 tele-photographic lens consists of the 2B. patent portrait (2½ inches diameter) in conjunction with a compound negative 1 inch diameter.

T. R. Dallmeyer.

THE CAMERA AND THE CONVENTION; OR, PICTURESQUE SCOTLAND AND PHOTOGRAPHY.

VI.

The Falls of Clyde will be remembered by many who were at the Glasgow Convention, and joined the trip to Lanark. Unfavourable weather always leaves a lasting impression, and, like the witches in *Macbeth*, we met "in thunder, lightning, and in rain." In fine weather, however, the Falls of Clyde are a very enjoyable photographic field, but only part of it could be well overtaken in one day. From Lanark you will get a vehicle to take you down to the gates of the grounds; but, if your apparatus is weighty, get your man to drive right in, if they will allow you, and, if not, have some one engaged to carry your traps, for some parts of the roads are hilly and rugged, and, if it is a hot day, it is very fatiguing. We have been there and found it so.

Lanark.

A good way to go to the falls at Lanark is by train to Hamilton and thence by coach. The first place of interest by this route is Tillietudlem Castle, which figures in Sir Walter Scott's *Old Mortality*. The ruins of this castle are on the hill about a mile and a half from the high road. Your conveyance is left at a wayside inn, and the approach to the castle is made on foot, by the side of a glen most of the way, very picturesque, well wooded, and full of charming studies. The last time we were at Tillietudlem the castle was surrounded with fruit trees, rich in blossom, and all the ground was carpeted with the fallen blossoms. Some good negatives are to be had here, but we would warn you that it is a considerable pull up the hill if your apparatus is heavy.

Next we come to Stonebyre's Fall, which is within four miles of Lanark. There is considerable difficulty at this fall in getting sure footing at suitable places for the most effective pictures. It is the largest fall, and the volume and rush of water to be seen here when fairly full is magnificent. Still it is not easy to get at, and needs a little nerve.

From here we drive right on to the town of Lanark. It is of interest as a town, being the place where Wallace, the hero of Scotland, began his career. And Wallace's Cave is still shown on the Mouse Water, about a mile north-west from Lanark.

From the hotel at Lanark, you will get a conveyance to carry you to the Falls of Bonnington and Cora Linn. A day's work is to be had at and around these two falls; everywhere we turn the glen and grounds are one succession of beautiful panoramic pictures. Cora Linn is the first fall reached, and good positions for effective pictures of this fall are easily obtained. The Bonnington Fall is also easy of access.

For pictures of fall, and rushing stream, and rich woodland scenery, those that are to be found here, amidst the mighty sound of ceaseless falling waters, are unsurpassed.

If the falls are to be visited by rail instead of driving from Hamilton, the journey to Lanark is twenty-five miles from Glasgow.

Ayr.

The town and district of Ayr is looked upon with intense interest and pleasure by every lover of Robert Burns', Scotland's son of song, and we believe every Scottish heart warms at the mere mention of his name. Ayr is about forty miles from Glasgow. The town itself possesses some points of interest, such as the Wallace Tower, in the High-street; and before reaching it, on the same side of the street, is the "old pub" where Tam O'Shanter and Souter Johnnie did carouse on that night when Tam got such a fleg at Auld Alloway Kirk, and just saved himself at the expense of his auld mare's tail. Then there's the "Twa Brigs" and the "Fort of Ayr," and the River Ayr, up beyond the station a mile or two, is rich in pictures. Burns' birthplace is not more than two miles from the town. This, and the Auld Alloway Kirk, Burns' Monument, and the auld Brig o' Doon are all within a quarter of a mile of each other.

There is a new Brig and the auld Brig, and a little house, with some statuary and relics of Burns, and Burns' Monument, all within the grounds at the back of the hotel, and all quite convenient for photographic purposes. And up the river, beyond the Auld Brig, there are some old mills and other quaint studies.

When at Ayr we drive to the Brig of Ballochmyles. Here we can get some good river pictures. This ground is also closely associated with Burns' life, for the Braes of Ballochmyle are only about two miles from Mossgeil.

Coaching Tours.

Just as we write, we see that there is a series of new coaching tours being started in Ayrshire for the summer months. Intending tourists take train from Glasgow to Ayr, reaching Ayr early in the day, where a char-à-banc, a vehicle arranged for twenty passengers, awaits the arrival of the train, and takes one of three routes, as it is arranged to go to one of the following each day:—Straiton, Culzeau, or Ballochmyles, returning

to catch the train at Ayr in the evening. Either of these excursions would take the tourist through some of the most charming scenery in Scotland. The only thing we doubt is that the journey being done against time, so to speak, there will not be opportunity to photograph as much as one would like. We have gone over a considerable portion of the ground that these tours intend to embrace; but we had lots of time to look round and photograph, and, under these circumstances, had a good holiday.

Water Excursions.

From Glasgow the outings that appeal most to the stranger, and those that are mostly taken advantage of, are the "Doon the Water" excursions. There is a story told about a Paisley weaver, on board of one of the river steamers, who, on going down to the cabin for a drink, called out, "Steward, steward! mind you cry me up whin the scenery begins!" And we sometimes think that there is more than the weaver possessed with this idea, for the tourist in his haste usually takes the train to Greenock or Gourock, and catches up the boat at either of these places, so that he may be launched into the picturesque at once without having the labour of gradually approaching it. We believe, however, that the stretch of river between Glasgow and Greenock possesses many pictures and effects that in such a hurry are lost to the tourist.

From Govan, down both sides of the river, for these first twenty miles there are endless and ever-changing bits of scenery, that in a region less wealthy in beautiful effects would be hailed as charming.

We have done a good day's work at and around Renfrew, and on the Blythswood Estate, a little further down on the same side, while on the opposite shore is old Kilpatrick, with the canal behind [the houses, and the old boats slowly moving on its sleepy surface onward to the Clyde. Then lower down lies Bowling, which would well repay a visit; and Dumbarton Rock and Castle, from shore or river, is well worthy of a plate or two.

Greenock.

And now we come to Greenock. The Greenock piers are much frequented by the photographers who delight in instantaneous pictures. The old piers, Prince's Pier, and the new landing-stage at Gourock, give plenty of choice for this class of work. Moving steamers and boat pictures generally may be easily had from any of these points as well as the Esplanade at Greenock.

Everything will be found to make work easy, the river at these points being narrow enough to allow of getting a suggestive distance introduced, obtained from the hills and foliage on the further shore. On the quays themselves the traffic is constant and ever-changing, and, like the bits of glass in a kaleidoscope, the moving groups are ever taking new forms. Photographically, the town of Greenock is not of much count. Burns' Highland Mary is buried here, and Greenock was the birthplace of James Watt.

Gourock.

Gourock stands next to Greenock, on the same shore; but this side of the Clyde does not lend itself so much to the excursionist out for the day, who desires, when reaching the scene of action, to have the picturesque ready to his hand. One really romantic glen and dell, however, is to be found between Gourock and Wemyss Bay at Inverkip. For river scenery it is a gem in a foliaged setting between two hills.

Wemyss Bay in itself possesses some good points for water pictures, but for landscape views it shelves too much to the sea. Largs is also barren of any wide range of picturesque photography. We have taken the train from Largs to West Kilbride, and walked back by the seashore to Fairlie, and we found this ground rich in seascapes and rock effects.

Coming further round the coast, we touch at Ardrossan and Saltcoats, both of which places—leaving the sea out—are too towny for effect. Good shipping is sometimes to be had at Ardrossan.

RELATIVE EXPOSURES FOR VARYING PROPORTIONS OF IMAGE TO THE ORIGINAL.

[Photographic Society of Great Britain.]

When an enlarged photograph has to be made, either from a negative or print, it is commonly understood that the greater the degree of enlargement the longer will be the exposure required, but I have generally found only the vaguest ideas to exist as to the amount by which such exposure has to be prolonged. Sometimes, indeed, it is assumed that the exposure will be in direct inverse proportion to the area covered, so that a copy of twice the linear dimensions of the original—covering, as it does, an area of four times the size—would require an exposure of four times that sufficing for a copy of the same size. This calculation, however, omits to recognise an important factor, and leads to serious error; the actual exposure required in the case mentioned (assuming the same lens and stop to be used), being not four times, but two and a quarter times that of a copy of same size; whilst, when we come to high degrees of enlargement, the error would amount to an indication of nearly four times the exposure actually required.

To find the relative exposure, add one to the number of times that the length of the original is contained in the length of the image, and square the sum. This will give the figure found in the third column of the annexed Table.

Proportion of image to original (linear).	Distance of image from lens* in terms of principal focus.	Proportionate exposures.	Exposures proportioned to that required for copying same size.
$\frac{1}{30}$	$1\frac{1}{30}$	1·07	·27
$\frac{1}{20}$	$1\frac{1}{20}$	1·10	·28
$\frac{1}{10}$	$1\frac{1}{10}$	1·21	·3
$\frac{1}{8}$	$1\frac{1}{8}$	1·27	·31
$\frac{1}{6}$	$1\frac{1}{6}$	1·36	·34
$\frac{1}{4}$	$1\frac{1}{4}$	1·56	·39
$\frac{1}{2}$	$1\frac{1}{2}$	2·25	·56
$\frac{3}{4}$	$1\frac{3}{4}$	3·06	·76
1 (Same size)	2	4	1
2	3	9	2·25
3	4	16	4
4	5	25	6·25
5	6	36	9
6	7	49	12·25
7	8	64	16
8	9	81	20·25
9	10	100	25
10	11	121	30·25
11	12	144	36
12	13	169	42·25
13	14	196	49
14	15	225	56·25
15	16	256	64
16	17	289	72·25
17	18	324	81
18	19	361	90·25
19	20	400	100
20	21	441	110·25
21	22	484	121
22	23	529	132·25
23	24	576	144
24	25	625	156·25
25	26	676	169
26	27	729	182·25
27	28	784	196
28	29	841	210·25
29	30	900	225
30	31	961	240·25

As examples: supppose a copy is wanted having twice the linear dimensions of the original. Take the number 2, add 1 to it, and square the sum, $3^2=9$. Again, if a copy is to be of eight times the linear dimensions of the original, take the number 8, add 1, and square the sum, $9^2=81$. Copies respectively twice and eight times the size (linear) of the original will thus require relative exposures of 8 and 91—*i.e.*, the latter will require nine times the exposure of the former.

It is convenient to have a practical standard for unity. An image of the same size as the original is a familiar case, and serves as such standard. By dividing the figures in the third column by four, we get at the figures in the last column, which represent the exposure required for varying degrees of enlargement or reduction, compared with the exposure for a copy of the same size.

The Table is carried up to enlargements of thirty diameters; that is about the amount required for enlarging a small *carte-de-visite* to life size.

The exposures required in reductions do not vary at all to the same extent that they do in enlargements. It has, therefore, not been thought necessary to fill in the steps between images of $\frac{1}{10}$ and $\frac{1}{20}$, and between $\frac{1}{10}$ and $\frac{1}{30}$ of the size of the original. Beyond $\frac{1}{30}$ there is scarcely any perceptible difference in the exposure until disturbance comes in from another cause, a considerable distance of illuminated atmosphere (haze or fog) intervening.

* With a double lens it is usually sufficient to measure from the position of the diaphragm plate.

The figures in the second column will also serve as a Table for distances from the lens to the plate and to the original, all that is necessary being to multiply by the principal focus of the lens in use. In the case of enlargements the figures less than 2 must be multiplied to get the distance from the original to the lens, and the figures greater than 2 for the distance from lens to image. For reductions, the figures less than 2, multiplied by the principal focus of the lens, yield the distance from lens to plate; and the figures higher than 2, similarly multiplied, give the distance of original from lens.

W. E. Debenham.

ADVANCED PHOTOGRAPHIC WORK FOR AMATEURS.

II.

Let us now see how any lady or gentleman, who having made a small quantity of emulsion (it will be about six ounces), as described in the preceding article, should set about coating their first plates, and here I recommend their beginning with small sizes and only a very few just as a start until they get their hand in, when they will, no doubt, fly at higher game before long. To begin with, however, two or three at modest quarter-plates or, at the outside, three half-plates, only should be taken in hand, because there will be less likelihood of mess or failure than when larger sizes and greater numbers of plates are manipulated.

Begin, therefore, by having, say, three perfectly clean half-plate opals with matt surfaces on one side ready, place these in a flat tray containing hot water so as to keep them at a nice warmth when the emulsion is being poured on them. This done take a lump of the emulsion about the size of a small egg and melt it by placing the tumbler containing it in hot water, or it is better to use a glass graduate measure having a pouring lip. When the water is heated to 100 degrees Fahr. the lump of emulsion will be all melted, and after standing on the water for about five minutes the emulsion will be of the proper warmth for coating. Whilst the emulsion is being melted it is well that a moment's attention be given to a simple arrangement for holding the coated plates so that the emulsion will set perfectly even and flat. An ingenious mind will not be long in finding in any well-ordered household some suitable support for this purpose. I would, however, suggest a few old negative glasses of larger sizes, such as 15 × 12, or 12 × 10. When only small opals are being coated these levelling supports are easily set true with the aid of a common spirit level, which, doubtless, every amateur who has gone this far in photography will have at hand, if not, the sooner he gets one the better, and then let it be circular in form. Having, therefore, arranged for the setting of the plates when coated, let him proceed to take an opal from the dish of warm water in which they were placed, and with the aid of a clean, dry towel make the opal quite free of damp, both back and front and round the edges. This done, let the opal be taken between the forefinger and thumb of the left hand at the left bottom corner, and holding the plate as nearly flat as possible, with the right hand take the graduated glass measure containing the emulsion out of the hot water, and by placing the lip of the measure *quite close* to the surface of the opal quietly and slowly proceed to pour a *round pool* of emulsion on to the middle of the plate. A very slight practice will enable any one to judge of the size of the pool. Now, by gently tilting the plate, and by coaxing with the little finger of the right hand, which still holds the glass measure, the emulsion on the plate is coaxed to the four corners and over the entire surface. If it is judged that too much emulsion has been flowed on, a very slight tilting of the plate will enable a portion to be run off into the measure. The plate is then coaxed till the surface is evenly covered, and without delay placed on the levelling stand. Meantime, the glass measure containing the emulsion has been reset in the hot water to keep the contents at an even temperature until all the plates are coated in a similar way.

Now, when gone about deliberately there is no mess or difficulty in coating a plate with emulsion in the manner I have described. I feel the great secret of success lies in having the opals slightly warm, or, at least, with the chill off, as the saying goes, and this is done best by keeping them in warm water till required. Next, the lip of the glass measure must be placed close to the surface of the opals when the emulsion is being poured. This prevents slopping, and avoids air bells, and also enables *a circular pool* to be formed, which will run over the surface of the glass much more easily than when such assumes every inconceivable shape. In a few minutes the emulsion will have set after being laid on the levelling plates, and the opals are ready for drying. All this work is done by ordinary gaslight.

T. N. Armstrong.

Our Editorial Table.

A Manual of Photography.

By A. Brothers, F.R.A.S. London: Charles Griffin & Co., Limited.

Mr. Brothers has had such a large and varied experience in photography that any work by him on the subject cannot fail to prove interesting and valuable. The present is a most comprehensive volume, commencing with the early history of the art, and taking us progressively up to the present time, entering with full details into the various processes now or formerly extant. The chemistry and optics of photography—the various artificial lights—the apparatus—the materials employed—the applications of photography—these and other similar topics form the divisions in this work. It is very fully illustrated, both with woodcuts and full-page examples of photogravure, chromotype, Meisenbach, examples of Boussod, Valadon, & Co.'s work, photo-lithography by Messrs. A. Brothers & Co. and others, half-tone zinc etching, Woodburytype, and several other processes. The text portion winds up with a collection of practical hints of great value. It is a handsomely printed volume and admirably got up. 364 pages.

We have received from the Fry Manufacturing Company a uranium toned print on their "Roughest" bromide paper. The subject is *Going out to Sea*, by A. J. Golding, which took a prize at the

recent Holborn Camera Club Exhibition. The negative must have been a fine one. The composition is shown by the reduced etching here given, and the picture is a charming example of the process.

Improvements in Letterpress and Lithographic Processes based upon Photography.

No. 6571. Eugene Albert, Schwabing, near Munich, Germany.—*April* 16, 1892.

This invention relates to improvements in letterpress and lithographic processes based upon photography.

Photo-lithography and half-tone blocks for the letterpress are produced as follows:—When taking a photograph of an object, a glass plate supplied with the requisite lines or grains is placed before the sensitive film, and then the negative is exposed through this net or tint. Owing to the solarisation, or extension of the action of the light sideways, being proportional to the values of lights and shades, the half-tones of the original are divided into bigger or smaller lines and points. From such a negative, composed of lines and points, the transfer on stone or metal is made, and subsequently the etching takes place in the known manner.

The result of this etching, as far as it is mechanical and without any art manipulation, is only based upon the usual big or small lines and points of the given negative according to the lights and shades of the original.

The size of the points, without regard to the character of the original to be reproduced, depends on the number of lines to the millimetre, and on the proportion of the white and transparent lines to the black and covered ones on the line plate or tint.

The number of lines to a millimetre ranges from 5 to 8; with a larger number the printing capacity of the blocks is prejudiced, and with a smaller number the richness of tone is diminished. This drawback arises as follows:—

Supposing the proportion of the white to the black line be 1 : 1, the solarisation, with a certain size of the net or tint, would no more suffice to contract enough in the lights the transparent points on the negative, while the covered point attains in the shades considerable dimensions, owing to the wide meshes of the line plate or tint. Consequently the lights, after etching, are too dark and without any effect, while in the deep tones a middle grey is observable immediately beside the completely dark. If in the net or tint the proportion of the black to the white line were altered in favour of the latter, the lights would, of course, profit thereby, but the shades would be greatly damaged. A larger black line would give better shades, but no lights.

It is, therefore, impossible to produce, by a coarse line, plate blocks of good effect and rich in tone, which would be adapted for printing on common placard or poster paper, and for illustrations of daily newspapers, &c. It is still a great drawback inherent to the photographic line plate or tint process, that good results regarding the soft and plastic shades, the tender half-tones,

and the great clear lights, can only be attained if the originals are well qualified for this purpose.

In order to always ensure the said advantages even with unfavourable originals, and with any net or tint, it is necessary to employ for the different tones of an original also different line plates or tints in such a manner that, for the shades, the black lines are larger than those for the lights, and for the lights the white lines are larger than those for the shades.

Such an ideal, impossible as it seems, can be attained by the gradual line plate, or scale net, or gradation tint forming the subject of this invention. A gradual line plate or gradation tint can be produced in different ways; but the most simple and accurate manner is the following:—

To prepare the negative for the reproduction of an original net or tint, the lens is put in communication with a screw, the revolutions of which can be controlled by a counter. The principle of this manipulation is founded on the parallel displacement of the lines. The very small degree of such displacements necessitates accurately executed mechanism, which, for instance, would render a movement of one-hundredth of a millimetre determinable.

A gradual line plate or gradation tint may be, for instance, produced and applied as follows:—

The original line plate or tint, in which the light and dark lines are supposed to be in the proportion of 1 : 1, is focussed in the usual manner, and the objective adjusted in the above-mentioned machinery. After the sensitive plate has been put in place, the exposure is commenced, which, to obtain the necessary effect for the net or tint negative, may be supposed, in this instance, to last altogether six minutes. After the lapse of three minutes, the exposure is interrupted, and the objective displaced by means of the screw to such an extent as would amount to half the thickness of the lines. Subsequently, the exposure is continued for another three minutes, and then the plate developed and fixed. Each single line of the negative thus produced has two tones, viz., a grey tone and a black body in the middle thereof. As after three minutes' exposure the objective was displaced only by half the thickness of a line on the negative, the second half of the six minutes' exposure was, for one-half of the line, a continuation of the first exposure, which accounts for the black body in the middle of the line of the negative.

If the white line on the original line plate or tint was equal in width to the black line, the displacement has now caused the grey line with black core to become broader on the reproduced line plate or tints at the expense of the white line, the proportion being now 3 : 1.

When reproducing an original by means of such a gradual line plate, or scale net, or gradation tint, the grey line forms an obstacle for all rays of least intensity from the deep shades of the original, and represents, in fact, an equivalent of the black line. The result is a broad dark line and a narrow light line in the proportion of three to one, which is favourable for the reproduction of the shades of an original.

The rays emitted from the half-tones of the original begin, corresponding to their intensity, to solarise about the grey line, while the rays from the lights are sufficiently intense to penetrate the grey line and find an obstacle only in the double film of the dark middle—that is to say, only the dark core avails for the lights; the grey line acts as if it were white, and the result is the most favourable proportion for the lights, viz., a narrow dark line and a broad light line in the proportion of one to three.

The number of scales or gradations may, of course, be increased according to the subtleness of the mechanism or size of the net or tint. The desired gradations can also be produced photographically by other means, such as, for instance, according to the above-mentioned principle of the parallel displacement of the tint lines. It is also possible to produce an original gradation tint by any suitable direct mechanical means. The desired result may also be achieved by displacement of an ordinary tint consisting of dark and white lines put immediately before the sensitive plate during the exposure of an original, or by the displacement of the sensitive plate itself. The effect of such a displacement varies for the different tones of the original, because the high lights of the original produce a correspondingly intense action on the sensitive plate in a fraction of the time of exposure, the transparent points on the negative diminishing in accordance with the amount of the displacement. On the other hand, the dark parts of the original cannot produce a chemical action in a fraction of the exposure but only during the whole time of exposure, and therefore the covered points are accordingly diminished.

The new principle may be applied to simple as well as crossed line plates or line waves, and it comprises, for the usual size of nets or tints, an important perfection of the result by mere mechanical means, while, owing to the possibility of employing coarse line plates or tints, it opens to the photographic processes for typo and lithographic prints the new domains of placard or poster printing, illustrating daily newspapers, &c.

Having now particularly described and ascertained the nature of this invention, and in what manner the same is to be performed, I declare that what I claim is:—1. A tint, single or crossed, for photographic reproductions, with any number of gradations of tone in its dark lines or line waves, which gradations may be produced mechanically when making an original gradation tint, or which may be made by photography, from a tint consisting only of dark and white lines, substantially as hereinbefore described. 2. The displacing of the screen or tint, single or crossed, put directly before the sensitive plate during the photographic exposure of a picture, or the displacing of the sensitive plate itself, substantially as hereinbefore described.

Improvements in the Method and Apparatus for Producing Magnesium Flashlight.

(A Communication by Emil Wünsche, Dresden, Saxony.)

No. 6269. Newnham Browne, 73, Cheapside, London.—*May* 7, 1892.

In photographing living subjects by magnesium light, it is invariably found that the subject or subjects are adversely influenced as regards the photographing by the flame usually employed for igniting the magnesium powder. The disturbance of the subject by this flame is frequently the cause that makes the resulting picture defective.

To obviate this disturbing influence of the magnesium light, by dispensing with a flame for igniting it, is the object sought by this new method for igniting the magnesium powder.

According to this invention, the well-known paper-cased percussion caps, or other percussion caps or detonators of a like character, which ignite with a report when struck, say, by a hammer, are employed to ignite the magnesium powder.

This method only sometimes succeeds in igniting the magnesium powder (experiments tend to show that this takes place only in about four cases out of a hundred), but these can only be deemed accidental exceptions; nor is a materially better result obtained even when the magnesium powder is strewed near to or even upon the fulminant material.

The reason why ignition of the magnesium powder by these percussion caps so often fails the inventor thinks to be this, that, when the fulminant is exploded by a blow, its ignition is too rapid to be capable of communicating itself to the magnesium powder.

The inventor's endeavour, therefore, has been so to retard combustion of the fulminant that its ignition may, with reasonable certainty, be communicated to the magnesium powder.

This he obtains by substituting for the blow of a hammer the prick of a needle, which perforates the fulminant material. In this manner a small portion only of the said material is immediately ignited instead of the entire mass, and the combustion therefrom spreads to the remainder, thus taking place more slowly, and is with certainty communicated to the magnesium powder strewed upon the cap so that the magnesium becomes luminous.

Improvements in Photographic Hand Cameras.

No. 11,394. Fox Shew, 88, Newman-street, Oxford-street, Middlesex.—*May* 7, 1892.

The invention relates to improvements in photographic hand cameras of the character referred to in the Specification of Letters Patent granted to George Lowdon, No. 4102 of the year 1885, and has for its object, first, to enable lenses of different foci to be used with such camera as well as the ordinary fixed focus lens; and, secondly, to enable the back of the camera to be adjustably held within certain limits at any angle with the front thereof.

For this purpose I make the hinged sides or wings of the camera extensible by forming them in two parts, fitted together with groove and tongue joints; and, as the substance of the wood is small, I form the tongue of metal, preferably rolled brass, which latter is provided with two or more notches, into which a spring pin is capable of entering.

Thus, when using a fixed focus lens, the sides or wings are used in their normal or non-extended state; but, when using a lens of different focus, the extensible portions are slidden outwards from the fixed hinged portions, and are locked in the required position by the spring pins.

The outer ends of the sides of the hinged portions of the sides or wings are connected together by a metal cross bar, which greatly strengthens such parts, and, in combination with a projection on the sliding parts, acts as a stop.

The back of the camera is divided into two parallel frames, the forward frame of which has connected thereto the hinged sides or wings, whilst the rear frame has connected thereto the rear end of the bellows. I also fix to each side of the rear frame a toothed rack, the front portions of which, just in front of the front frame, are formed with a hinge joint made in the body of the rack, and having the meeting faces of the leaves formed at a slight angle with each other, so as to cause the outer portions of the racks to be sprung slightly inwards towards each other, thereby causing them to have a grip on the front frame when the latter is extended, and by this means assist in holding the parts firmly together. These hinge joints also permit the racks to be folded down on to the sides or wings when the camera is packed up for transport. The front frame is provided on each side with a pinion, by which the rear frame can be extended as desired.

I also provide each of said frames with a slotted plate and a binding screw, the binding screw of each frame acting to bind the slotted plate of the other frame, and, in order to enable such slotted plates to fold within the limits of the frames, I form them of L shape, the pin joint being near the extremity of the shorter arm and the slot in the length of the longer arm.

Meetings of Societies.

MEETINGS OF SOCIETIES FOR NEXT WEEK.

Date of Meeting.	Name of Society.	Place of Meeting.
June 13	Darlington	Trevelyan Hotel, Darlington.
„ 13	Dundee Amateur	Asso. Studio, Nethergate, Dundee.
„ 13	North Middlesex	Jubilee Hall, Hornsey-road, N.
„ 14	Derby	Smith's Restaurant, Victoria-street
„ 14	Great Britain	50, Great Russell-st. Bloomsbury.
„ 14	Manchester Amateur	Lecture Hall, Athenæum.
„ 14	Stockton	Masonic Court, High-street.
„ 15	Bury	Temperance Hall, Bury.
„ 15	Manchester Camera Club	Victoria Hotel, Manchester.
„ 15	Photographic Club	Anderton's Hotel, Fleet-street, E.C.
„ 15	Portsmouth	Y.M.C.A.-buildings, Landport.
„ 15	Southsea	
„ 15	West Surrey	St. Mark's Schools, Battersea-rise.
„ 16	Brixton and Clapham	Gresham Hall, Brixton.
„ 16	London and Provincial	Champion Hotel, 15, Aldersgate-st.
„ 16	Oldham	The Lyceum, Union-st., Oldham.
„ 17	Cardiff	
„ 17	Holborn	
„ 17	Leamington	Trinity Church Room, Morton-st.
„ 17	Maidstone	"The Palace," Maidstone.
„ 17	Richmond	Greyhound Hotel, Richmond.

LONDON AND PROVINCIAL PHOTOGRAPHIC ASSOCIATION.

JUNE 2,—Mr. A. Cowan in the chair.

AMERICAN VISITORS.

Miss Catharine Weed Barnes, New York, Mr. J. Carbutt, and Mr. F. E. Ives, Philadelphia, were present at the meeting to which they were welcomed, in a brief speech on behalf of the members by Mr. J. Traill Taylor. At a later stage of the proceedings,

Miss BARNES, in reply to the Chairman's invitation to speak, said she had come to the meeting to learn and not to teach. She was anxious to take back as much of the country on her plates and to do as much with her camera as possible during her stay. She regarded it as a great privilege to be present. She had had the pleasure of seeing some partial tests of Mr. Dallmeyer's tele-photo lens and was exceedingly interested. In the April number of her magazine (the *American Amateur Photographer*) she had reproduced some illustrations done by means of Dr. Miethe's tele-photo lens, but she had much wanted to hear Mr. Dallmeyer's side. As an American she loved fair play and liked to hear both sides.

THE BLACK FLASH—REVERSAL.

Mr. J. S. TEAPE referred to Mr. Clayden's experiments which had been carried out to endeavour to prove the cause of the black flash in lightning discharges. Mr. Clayden had given a plate a short preliminary exposure and then exposed it to the electric spark; on that plate he had obtained no reversal—that is, he obtained a positive image, as was to be expected. He also exposed part of the same plate, which had had no preliminary exposure, to the same spark, with no sign of reversal. He then exposed a plate to the electric spark first, and gave a subsequent faint exposure, and always obtained reversal of the image. He (Mr. Teape) had made some experiments which were beyond doubt very exact, as they were all on one plate. He took an Ilford ordinary plate and first wanted to find the amount of light which would give reversal. He covered it with an opaque screen with eight openings in it, and exposed from one-inch to eight inches of magnesium to it, at twelve inches distance, and of course found where the reversal was obtained. One inch gave a faint sign of reversal and three inches clear glass. He took another plate and covered half of it with opaque material, and gave a preliminary exposure of one-quarter of an inch of magnesium at four feet distance, and then put it behind the same screen. Wanting to find out whether the subsequent or preliminary exposure hastened reversal, he gave an exposure to start with a little less than had actually produced reversal on the test plate. He started with three-quarters of an inch at the same distance, and gave the same exposure to the same opening of each half of the plate: three-quarters of an inch, one inch, one and a half inches, and two inches. To the covered-up half, which had had the preliminary exposure, he gave a quarter of an inch at four feet as a supplementary exposure. Developing with Thomas's hydroquinone developer for five minutes, he found no difference whatever in the three results—subsequent, preliminary, or simple exposed plate. He was quite unable to account for Mr. Clayden's results.

The CHAIRMAN observed that those results had not been borne out by Mr. Teape's experiments.

THE TELE-PHOTO LENS.

Mr. T. R. DALLMEYER said that, as the tele-photo lens had already been fully described, he did not propose to give a set paper on the subject, but he would show them a number of results which had been produced by it. It was well understood that a negative lens to increase the size of an image was employed many years ago in connexion with telescopes by Peter Barlow. That lens was of considerable use, but the limits within which it could be used for purposes of enlargement were certainly small. The first lens in which a negative element of moderate power was employed was the orthoscopic lens of Petzval. In that lens he employed a positive front element, which was very much under-corrected for positive spherical aberration, and corrected it by the back lens. The negative lens in the orthoscopic was of larger focus—about twice—than the positive element. The orthoscopic gave a magnification equal to that of a longer-focussed lens. It was originally intended for the cure of distortion. The next movement was in connexion with Derogy's lens. He employed between the two elements of a portrait combination a moderately powerful negative lens actuated by rack and pinion, which gave a certain amount of choice as regards focus. The next step was in connexion with Dallmeyer's triple achromatic, the negative being placed between the two lenses in a fixed position, and absolutely curing distortion. He believed this was the first lens in which distortion was absolutely cured. Having described the first form of tele-photo lens which he had introduced, he said that in the new lens the positive element, instead of being of a single cemented aplanatic form, was a complete portrait combination, corrected as far as practicable throughout its whole field. The negative element was a symmetrical combination, also aplanatic. When the rays from the positive element met the negative element they were corrected very well throughout a large field and distortion was reduced to a minimum. Analysing this negative lens, they would find it a large fraction of the front as regards focus. The negative lens was of large aperture and short focus, and took in a comparatively large angle. With a smaller aperture and longer focus the angle and rapidity would be much reduced; with a bigger negative instrument the angle included would be very small. A feature of the back combination of the portrait lens was that by moving the back lens correction for near and distant objects was obtained. The lens could be always worked at full aperture with perfect sharpness on all planes. He had prepared a table of various extensions of camera and the corresponding foci, giving the circle of illumination and intensities at full aperture [see p. 377]. As to the higher degree of magnification claimed for Dr. Meithe's lens, it was a simple matter to use an exceedingly small and high-power negative but the loss of light and rapidity was so great as to make it absolutely worthless to cover any angle. They could never think of making an instantaneous exposure with it. In conclusion he said he believed the "sensuous impression" conveyed by the tele-photo lens was appreciated. They got an image equal in size by going nearer with a short-focus lens, but the perspective would be wrong. By getting farther away they did not get this exaggerated perspective.

Mr. Dallmeyer handed round some pictures taken with the tele-photo lens by Mr. McKenzie, of Glasgow, together with some of the recent eclipse. In reference to a batch of negatives which he also passed round, he indicated some to show that density could be obtained without difficulty in these enlarged pictures.

Mr. J. TRAILL TAYLOR said Mr. Dallmeyer had given Derogy credit for introducing a negative combination, but he (Mr. Taylor) would like to place it on record that the first to introduce it in this country to lengthen the focus of a lens was the late Frederick Scott Archer; Goddard was the first to improve upon Sutton, who introduced a negative lens to flatten the field and cure distortion, the negative being placed in the centre of two achromatised plano-convexes, Goddard making the positive lenses of a meniscus form. The Photographic Society of Scotland had tried it very carefully, and it was the only lens they had access to which gave absolute freedom from curvilinear distortion. As a set-off to this, however, it had a diabolical flare spot. There was something Mr. Dallmeyer had forgotten to say, and this was, that he had made his amplifying lens with its first surface convex, and that rays from the portrait combination fell upon it normally. There was a considerable difficulty in getting vigour and force in negatives taken from a distance, owing to aerial perspective. He had had a deal of difficulty to cope with in getting vigour, on account of tremor or waviness in the atmosphere caused by the heat from the chimneys. He recommended those who tried this lens to keep away from London as much as possible.

Mr. W. E. DEBENHAM said that Mr. Dallmeyer said it was impossible to correct a lens for near and distant objects. What would he call a near object?

Mr. DALLMEYER said the other side of the room. The lens was considerably used for life-sized objects. Mr. Taylor's lens was of the Petzval form, which might account for the defect he complained of.

Mr. TAYLOR observed that Mr. Dallmeyer would not recommend the negative attachment for use with a rapid rectilinear lens, but he (Mr. Taylor) had tried it and found it answer wonderfully. It was a mighty improvement with regard to portability, but he had to pay for it by giving a longer exposure. The drawback was that one had to make the adjustment once for all. Could Mr. Dallmeyer suggest how to get over the difficulty?

Mr. DEBENHAM said Mr. Dallmeyer had said that the use of a diaphragm would make the field much smaller. Suppose the diaphragm was close against the negative lens?

Mr. DALLMEYER said little benefit would be got from that, as the angle would still be reduced.

Mr. DEBENHAM said that, in regard to tremor, there was another cause than heated air, and that was from the tremor of the instrument itself or the camera.

Mr. DALLMEYER said that with the tele-photo lens a draw of camera eighteen inches represented a focus of seventy-two inches.

Mr. DEBENHAM considered it desirable to impress upon users of the lens to have a rigid stand and not use it when the wind was about. He had examined the lens and found that the field was distinctly convexed.

Mr. J. CARBUTT having exhibited the Genie hand camera and the Henry Clay 7×5 hand camera, as well as some very large pictures taken on his films, votes of thanks were passed to him and Mr. Dallmeyer, and the meeting closed.

Holborn Camera Club.—June 3, Mr. R. Luxton in the chair.—Mr. WEST opened a discussion on *Landscape Photography*. He confined himself strictly to artistic productions. He did not for one moment think photography was a high art—it was impossible to be so; but a man with a little bit of the artist in him, and who was conscientious in his selection of the subject and the way he carried it through the after-processes, might, if not to make photography a high art, very near approach it. He proposed to give them his idea of the composition of a landscape picture. A picture should appeal to one's artistic feelings, and a knowledge of composition was very important if a picture was to be turned out. He put the chief rules of composition before those present, and gave illustrations which clearly interpreted those rules. He made a special point of the three planes, foreground, middle distance, and extreme distance. He gave a few hints on exposure, and then dwelt on the developing portion of our work. A perfect knowledge of the capabilities of the different solutions which formed the developer was essential. He gave broad lines for proceeding to develop; but, as every plate required a different mode of treatment, it was extremely difficult to give information on strict lines. They must go cautiously to work. The last and most important part was the printing of the negative. Whether it was printed in bromide, silver, matt surface of glossy, it should suit the subject. The chief end in photography was the finished print. What did it matter if the negative was not technically correct if the resulting print was right! An interesting discussion followed. Mr. Raphael showed a hand camera called the "Surprise," which had a very original changing arrangement. Members are requested to take notice that the Pinner outing is postponed to the following Saturday, June 18, the the members being invited to a tea at the "Green Man," Mill Hill (Edgware), on Saturday, June 11, by Mr. C. O. Burgess, the President of the Holborn Cycling Club.

South Manchester Photographic Society.—May 30, Mr. W. I. Chadwick in the chair.—Messrs. J. Aitchison, jun., and J. Wild were elected members. The CHAIRMAN presented the Society with an enlarging lantern, and, in the course of his remarks, said that, although bromide enlargements were very nice if well done, still he did not think that the results could compare with those obtained either by the platinotype or carbon processes. The thanks of the Society were awarded to Mr. Chadwick for his present, and Mr. Linnell, in proposing the same, said he hoped the members would make good use of it. Results of the Millers' Dale ramble were then shown by several of the members, chiefly in the form of stereoscopic transparencies, and were pronounced to be very successful. Mr. Linnell also exhibited the negatives which were taken on Edwards' films, and, in the discussion that followed as to the relative advantages of films and glass, it was proved that results were quite as satisfactory, and, as regards the weight, one dozen 6½×4¼ films, with packing, weighed five ounces, whereas one dozen plates same size weighed forty ounces. In one case

he cut the film in two, and transposed the parts, with the result that a stereoscopic transparency could be obtained from one printing. Messrs. Mawson & Co.'s "Radial" and "Metal Miniature" hand cameras, along with Hurter & Driffield's actinograph were laid on the table for the inspection of the members. Specimen photographs on Fry's roughest bromide and soltype papers were also shown. Exposure notebooks sent by Messrs. Mawson & Swan were distributed. In the absence of Mr. Wilkinson, the Secretary exhibited the Beard-Pringle lantern, which was very much admired for its compactness. Slides done by the members were then projected on to the screen by its aid, some of the work being very good. An adjournment was then made to the lecture-hall, when some beautiful flash-light pictures taken behind the scenes during the two last pantomimes at the Comedy Theatre by Mr. Wade, President of the Manchester Amateurs, were shown by aid of the lantern, and some American views brought by the Chairman.

Correspondence.

☞ *Correspondents should never write on both sides of the paper.*

HELIOCHROMY.

To the EDITOR.

SIR,—From your issue of June 3 I learn that Mr. Ives continues to judge of my process of heliochromy from faulty translations of my paper of 1885, and maintains his assertion that the friendly, cordial, *private* correspondence over orthochromic matters between Professor Himes, Philadelphia, and me, should have been an official one, in the name of the Franklin Institute.

In reply to this I remark that, if I could have known that my private correspondence would have been recognised as an official one, I would have given Mr. Himes much more information for the decision of the priority than I have done. Therefore the verdict of the Franklin Institute in the matter is valueless for lack of full information from my side.

Mr. Ives asserts that he has published "the first successful method" for taking orthochromic pictures by the chlorophyll process, and degrades mine. I answer that I published already (1883), six years before Mr. Ives, my method for taking colour pictures successfully by corallin and collodion; that (1878) Ducos du Hauron, in his "Traité pratique de photographie en couleurs," Paris, Gauthier-Villars, p. 24, published a chlorophyll process one year before Mr. Ives. Ducos du Hauron gave up this chlorophyll process *in favour of the eosine process* Mr. Ives degrades.

Indeed, all reproduction galleries of Europe and America work with the eosine process, or the eoside of silver process, but nobody with Ives' chlorophyll process, which has only an historical interest on the other side of the water, in circles where European investigations are ignored in favour of American ones.

Mr. Ives asserts further that he already published his new (?) process of photography in natural colours in 1888. I reply that my process was published in my book, mentioned on page 318 of this JOURNAL, already three years before Mr. Ives'. The fact remains uncontradicted that Mr. Ives totally misunderstood this process of mine, and has given a totally wrong description of it in the *Journal of the Franklin Institute*, January, 1891.

It is also wrong if Mr. Ives says that I "ignore the heliochromoscope altogether." On the contrary, I acknowledged it, p. 318 of this JOURNAL.

At the end of his letter, Mr. Ives says, "Dr. Vogel has a right to quote . . . . the *only* unfavourable expression of opinion of my lantern projections," &c. In reply to that, I call the attention to a second unfavourable expression over Mr. Ives' performance in the *Photography*, p. 292, wherein it said, "We must confess we were somewhat disappointed," &c.—I am, yours, &c.,

DR. H. W. VOGEL.

Berlin, June 5, 1892.

To the EDITOR.

SIR,—In his reply to my article entitled, "Projections in Natural Colours," Mr. Ives makes some statements which go wide of the mark.

First, He commences by asserting that he did *not* use red, yellow, and blue glasses in 1888. As I have never stated that he did so, this assertion is quite uncalled for.

Second, He states that he did not then use three lanterns but one lantern, with three optical systems close together and a triple jet. I presume by a triple jet he means an arrangement of three limelights controlled by one pair of taps. This bears out my statement that he used three complete lantern systems with three limelights, what is generally called a triunial or triple lantern.

Third, He says he did not use three slides, but one slide carrying the three pictures. As his negatives were on separate glasses, it is clear that the transparencies were also on separate glasses in order to admit of correct registration, hence he must mean that the three slides were mounted in one frame. This is practically admitting that his three positives were on three separate glasses, which was what I stated.

Fourth, He states that he tried making the negatives ten years ago on a single plate, but abandoned the plan in favour of separate glasses for the three negatives. This proves my statement, that In 1888 he was making each set of negatives on three separate glasses. It also proves that, prior to the publication of my improvements, he had not grasped the principle that the position of the three pictures photographed simultaneously on the one plate was precisely that which was required in order to secure perfect registration of the images on the screen. For example, in a view including a flagstaff it is obvious that the lines representing the flagstaff must be absolutely parallel to each other in the three positives. This parallelism is secured in the most perfect manner by taking the three pictures on the one plate simultaneouly.

After the publication of my improvements, Mr. Ives entirely altered his method of working. In June, 1891, he exhibited the new arrangement at the Franklin Institute. According to a report relating to this, "when Mr. Ives first published his process several years ago, the three negatives requisite were made in one camera from one and the same point of view, but last night he showed that, by an improvement on his heliochromic camera, the three negatives are now not only made from one point of view by simultaneous and equal exposure, as they were three years ago, but also upon a single sensitive plate. . . . The lantern front used for these new projections consisted of three prisms, converging light from a single condenser, and radiant to three small projecting lenses." The latter sentence indicates that he was then using a lantern employing a single source of light for projecting several pictures, an idea which he admits originated with myself.

Mr. Ives is welcome to adopt my improvements in his own country; but, when he exhibits his results in England without giving the slightest hint that there are patent rights attached, it is needful for me to protest.

Mr. Ives asserts that the process has failed in my hands, because the three images, being taken from slightly different points of view, will not perfectly register on the screen. Six months ago I devised an arrangement of lenses whereby the pictures are taken from points of view only half an inch apart, so this small defect is corrected.

Mr. Ives' heliochromic process and Scott's "Verak" system are now practically one and the same thing; so, if the one is a "failure," the other must be a failure also.—I am, yours, &c.,

ALBERT W. SCOTT.

401, *Cowbridge-road, Cardiff.*

To the EDITOR.

SIR,—In your issue of May 13 appears a letter from Dr. H. W. Vogel, objecting to my remarks about Mr. F. E. Ives in a lecture on April 5 last, as follows:—"When, about thirteen years ago, Mr. Ives undertook to reproduce, by means of photography, the colours of nature, he fully realised that no light task was before him."

In stating that this remark is strictly true, I wish to add that, if Mr. Vogel will now undertake to produce results equally as true to nature as those recently shown by Mr. Ives in London, I am quite sure, if he will ignore entirely the ingenious devices of Mr. Ives in colour photography, he will find that he has "no light task before *him*." Until then, "'nuf ced."—I am, yours, &c.,

W. N. JENNINGS.

Franklin Institute, Philadelphia, May 27, 1892.

THE CONCENTRIC LENS.

To the EDITOR.

SIR,—I gave you the result of the trial of the new concentric lens some weeks ago, and since then have had the lens opened up to *f*-11 and *f*-13, and send you impressions of the negatives obtained. With *f*-11 the focussing is difficult—why I cannot say—and naturally there is not the same range in the depth of the focus; but *f*-13 works perfectly, and, though No. 3 is a poor print, you can see that the definition is as good as need be, and the exposure—the shortest I could get with the convenient little shutter of Perkin, Son, and Rayment—gives me figures in motion, and if I could have diminished the exposure considerably it would still have been enough. I get so little time for experiments that I have not been able to make another trial with an opening of *f*-16, which I think would be sufficient with the same conditions. In No. 1 (*f*-11) the extreme distance is woolly, which is not the case always with that stop; but I cannot say why. I suppose the reason is that the granulation of the focussing screen is too confusing, for I find it very difficult to determine the focus for the granulation when I employ the magnifier, and find it safer to focus without it. Then with films I am not sure of the exact focus, as they sometimes curve a little; not enough to do any harm in ordinary cases; but with the stop of *f*-11 a very little variation does harm. We have no plates of English sizes here, and my camera does not take the French conveniently, so I am waiting for some good English plates to try the next experiments.

But I should advise those who wish to use the concentric for very short exposures to have it opened up to *f*-12, which it will bear perfectly for practical purposes on an angle of about fifty degrees, maintaining all the qualities of the lens. Nos. 1 and 2 were taken with the components separated about a half millimetre beyond the normal, but No. 3 with them in their proper place; and you will see the effect on the illumination, which is much more equal in the last. The lens is a seven-inch.—I am, yours, &c.,

W. J. STILLMEN.

Rome, May 29, 1892.

"COSMOS."

To the EDITOR.

SIR,—As one of the junior members of the London and Provincial Photographic Association, who are supposed by "Cosmos" to suffer from severe snubbings week by week, permit me to deny the truth of his assertions if applied to our Society. I look to the London and Provincial as my most valuable source of technical information, and I am bound to say I have always found our old and best-informed members ready to assist in solving a difficulty, even at the expense of considerable trouble to themselves. In linking Mr. Haddon's name with his gibes, your contributor is singularly unfortunate, because Mr. Haddon's reputation, as one who has made many valuable suggestions to photographers, is sufficient to refute the ungenerous sneer. And here, by the way, let me remark that Mr. Haddon's advice to amateurs, to make collodion positives for their friends, was rather for the benefit they would derive in studying the process. As further recommendation, he mentioned it might help to mitigate the injury done to professional photographers, and remove this slur from the amateur's name. But, reverting to the attack on old members of photographic societies, I would like to point out a remarkable contradiction. The credibility of a witness is dependent upon his truthfulness. What does "Cosmos" say to these quotations from his modest little jottings?—

THE BRITISH JOURNAL OF PHOTOGRAPHY, May 13, page 309:—"Not long ago I was present at a meeting of a photographic society."	THE BRITISH JOURNAL OF PHOTOGRAPHY, June 3, page 356:—"I have said I never go to any of the Society's meetings. Though once an *habitué* of several, I placed myself on the permanent absentee list several years ago."

Really, Mr. Editor, some persons should have long memories.—I am, yours, &c., JUNIOR.

London, June 4, 1892.

To the EDITOR.

SIR,—"Silver Bath" is pleased to inform "Cosmos" that in this particular case he does not live in a glass house, also to tell him that some old photographers were perfectly competent to verify the quality of the chemicals they bought. The average photographer of the early times knew much more about the materials he used than one of the present date, but if he trusted at times to the honour of so-called respectable dealers, and was deceived, where lies the blame? "Silver Bath" knew thirty years ago that silver nitrate was largely adulterated with potash nitrate, but this article was usually offered at a lower price to tempt the unwary; he knows that he did not fall into the trap. As he commenced photography nearly fifty years ago, he cannot be considered a tyro, and he does not wish to occupy space in THE BRITISH JOURNAL OF PHOTOGRAPHY to prove what was well known—the advantage of the use of recrystallised silver nitrate in making the bath over the commercial article.—I am, yours, &c., SILVER BATH.

June 7, 1892.

PHOTOGRAPHIC PRINTERS.

To the EDITOR.

SIR,—I have read with great interest your article and correspondence on "Photographic Printer." I am an operator, and find it equally as difficult to obtain a berth in that capacity as "Unfortunate" does as a printer. Now, I am not one to content myself with plodding along anyhow, but have made a careful study in all branches of operating, and have obtained the highest and most flattering of references from good firms, which testify to my skill as an expert photographer. If all employers were like your correspondent L. Hubert, I would have no difficulty in finding a berth. I am a competent operator, but not a first-class retoucher, worker in monochrome, water colours, black and white, &c. How can employers expect a man to have mastery over so many branches, as is too often required? Then, again, will not employers engage a man of thirty-five years of age who has taken up photography the last five in preference to another who, perhaps, is blessed with more brain power, and has eight years' experience, but is only aged twenty-five? The question is, Are testimonials of any use, and will age give brains? Is it not a fact, Mr. Editor, that a smart, energetic man will learn more in five years by exercising common sense and brain power than another who plods along in a mechanical sort of way for twenty years?

I have often had my application for a berth returned to me written across, "Not old enough for experienced operator," in spite of my exceptional references I am, unfortunately, only twenty-five years of age.—I am, yours, &c., AN OPERATOR.

June 4, 1892.

To the EDITOR.

SIR,—I notice in your last issue two letters from correspondents in reference to printers, in which one gentleman states no good worker need ever be out of work; but I beg to differ on that point. I am a printer (silver and platinum) with several years' reference from a leading high class photographer in London. For several weeks I have been out of employment. During that time I have advertised occasionally. The answers I often got were, "Thanks; your price is too high."

Now, sir, what kind of men do employers expect for the salary they offer? If they were to pay a fair and reasonable salary, they would have no difficulty in obtaining a good man; but, of course, they engage the cheapest men, and get the "incompetents and duffers," and then complain of being unable to obtain really good workers.

It is quite true there are vacancies every week, but not the vacancies an experienced man would apply for. The majority are as follows:—"Printer wanted, one able to operate and retouch preferred." After sending *carte* of self, specimens, and reference, they offer the enormous salary of 1*l.* per week, which barely keeps starvation away.—I am, yours, &c., F. L.

June 6th, 1892.

ORTHOCHROMATIC PHOTOGRAPHY.

To the EDITOR.

SIR,—I shall be glad if you will announce that the next ordinary meeting of the P. S. G. B. will be held here on Tuesday, June 14, when Dr. J. J. Acworth, F.J.C., F.C.S., will read a paper entitled "Orthochromatic Photography," with experimental illustrations.—I am, yours, &c., R. CHILD BAYLEY, *Asst.-Sec.*

50 Great Russell-street, June 4, 1892.

CORRECT EXPOSURES.

To the EDITOR.

SIR,—It is hardly fair to ask you for space to reply to Mr. Alfred Watkins' letter on this subject in your last issue, because, my reply will only amount to a repetition of my former statements on this question.

Mr. Watkins states my contention that a large amount of subject will transmit more light to the plate than a small amount quite correctly, but it seems an easy way of refuting that contention to state "the fallacy of Mr. Michael's argument is, in assuming that a large amount of subject will transmit more light to the plate than a small amount." Mr. Watkins makes no attempt to show wherein the assumption is fallacious, neither does he point out wherein the example I gave in my former letter is theoretically wrong.—I am, yours, &c., M. J. MICHAEL.

June 6, 1892.

THE PHOTOGRAPHIC CONVENTION OF THE UNITED KINGDOM.

To the EDITOR.

SIR,—I have the pleasure to enclose a further list of papers to be read at this year's meeting of the Convention at Edinburgh, which I hope you will publish for the convenience of those of your readers who are members. Professor W. K. Burton and Mr. F. M. Sutcliffe have also promised contributions, but the title of their papers are not yet to hand.—I am, yours, &c., F. P. CEMBRANO, JR.

The Art of Photography in Relation to Painting, by Mr. A. Burchett.
Direct Silhouette Portraiture (with lantern illustrations), by Mr. J. Cox.
On the Training of Photographers, by Mr. E. Howard Farmer.
The Use of the Colour Screen in Landscape Photography, by Mr. Charles L. Mitchell.

10, Cambridge-gardens, Richmond, Surrey, June 2, 1892.

CHRONOPHOTOGRAPHY.

To the EDITOR.

SIR,—An article on "Chrono-Photography of Star Transits" in the last-received number of the JOURNAL (May 13) prompts me to send you a pamphlet which may prove interesting to you and to your readers who have at heart the application of photography to scientific research.

The Observatory publication will explain itself fully. The authors, I believe, intend to bring out, in June or July, a report of still further applications of their Photochronograph, practically and theoretically successful.—I am, yours, &c. J. A. S. BROSNAN, S.J.

Woodstock College, Woodstock, Howard Co. Md., May 24, 1892.

[The work in question gives an illustrated description of the photochronograph employed, and details the results of a number of experiments made in photographing transits.—ED.]

Exchange Column

*** *No charge is made for inserting Exchanges of Apparatus in this column; but none will be inserted unless the article wanted is definitely stated. Those who specify their requirements as "anything useful" will therefore understand the reason of their non-appearance.*

Hand camera wanted in exchange for a brand new (patent) landscape whole-plate camera worth 7*l.* 10*s.*—Address, SEWELL BRADY, 1, Hungerford-villas, Long Ditton, Surrey.

Answers to Correspondents.

All matters for the text portion of this JOURNAL, *including queries for "Answers" and "Exchanges," must be addressed to* "THE EDITOR," *2, York-street, Covent Garden, London. Inattention to this ensures delay. No notice taken of communications unless name and address of writer are given.*

*** *Communications relating to Advertisements and general business affairs must be addressed to* "HENRY GREENWOOD & Co.," *2, York-street, Covent Garden, London.*

R. C. PHILLIPS.—Thanks. In our next.

PASTE.—Omit the acetic acid from your paste.

G. C. HANCE.—The sensitising solution named will answer for canvas.

SENOJ.—Better precipitate the gold by protosulphate of iron, and then redissolve it.

A LEVY.—We do not think that the lens mentioned would be at all suitable for your purpose.

RANGER.—Appliances for carrying hand cameras on tricycles are sold at most cycle warehouses.

OTHELLO.—1. The lens is of trifling commercial value. 2. Millet was the name of the maker.

MERCURY.—See the paper on "Photographing on Wood," by Mr. W. J. Rawlings, published in the JOURNAL of April 8.

MORTIMER FIELD.—The Meisenbach Company, of West Norwood, will probably be able to supply you with the kind of zinco blocks you require.

X. O. Z.—If only three sheets of paper can be toned with a fifteen-grain tube of chloride of gold, it shows that it does not contain the proper proportion of gold.

W. BOROUGH.—Mr W. T. Wilkinson has, we believe, recently brought out a work on the subject, published probably by Messrs. Iliffe, St. Bride-street, E.C.

ALF. A.—The prints in question are collotypes varnished with an aqueous solution of shellac, which gives them the appearance of being silver prints on albumen paper.

S. C. J.—You certainly have paid a very low price for the lens; but it does not follow that all low-priced lenses are incapable of producing good work. Yours may, perhaps, prove one of the exceptions.

T. SEDGWICK.—The spots on the films are due to the emulsion. It is no fault, as asserted, in the manipulation. There is no way of avoiding the evil in the development, as it exists in the film before the developer is applied.

J. E. LINDSAY.—If you wish to take landscapes only, and obtain the best results, by all means take a half-plate or larger camera, and work it on a stand. For this class of work excessively rapid exposures are of no advantage—often the contrary.

O. Q. P.—The cause of the converging perpendicular is that the camera was tilted when the negative was taken, and the swing-back not brought sufficiently, if at all, into use. This is not an altogether uncommon fault with some foreign views.

C. BINGLEY.—You are quite under a mistaken notion as regards the wet-collodion process for portraiture. For quality of results, that process has not yet been eclipsed, except in the matter of exposure. Yours is by no means an isolated opinion amongst modern photographers.

H. PAYNE.—Vulcanised rubber is useless for making a solution of indiarubber. Get some "masticated rubber," and dissolve in benzole to the consistency required. The simplest way to obtain a solution is to purchase a tin of rubber solution or paste, such as is used for repairing indiarubber goods, and thin that down with benzole.

BERTROS.—With your experience and credentials you would, we think, find the best opening in one of the smaller towns at the Cape, such as Johannesburg or Pietermaritzburg; there would be far less chance for you at the other places you name. The risks of finding an opening on arrival are so great that we cannot advise you thereon.

B. R. U. M.—Yours is quite a case for the gentlemen of the long robe. If you have been sold the business under a misrepresentation of the facts, and find the receipts were not anything like they were stated to be, the law will certainly give you redress. Until you have had legal advice, we should recommend you to withhold any further payments.

"R. A." feels aggrieved because we, in a sub-leader a few weeks back, said that many artists use photography largely to aid them in their work. It is a fact, nevertheless. Some pictures, by "good names" too, have been painted almost entirely from photographs. Of course painters do not admit this, but there is no reason why they should decry photography.

B. RAYMONT writes: "I have often seen it stated in print that by filtering a solution of brown shellac in methylated spirit, such as used for negative varnish, through animal charcoal it will be decolourised. I have tried this several times, but always found that no colour was removed. Where have I failed?"—It is a fallacy. The alcoholic solution of shellac is not decolourised by filtration through charcoal.

HANTS, writing in relation to a paper recently read before one of the London photographic societies, asks, when any one undertakes to read a paper on any subject with which it is well known he is familiar, if he should not give some details of the methods of working, instead of leaving that portion of the subject in the dark.—All we can say is that a little of the practical side of the question would have been very acceptable to the majority of those who were there. But, of course, it rests with the readers of papers as to what they will say. The societies cannot stipulate as to how the different subjects shall be treated. They, in most instances, are glad to get papers of any kind just now.

MELTONIAN asks, "Which is the best gelatine for Woodbury printing?"—If our correspondent means for printing the impressions from the metal moulds, then any gelatine of a strong kind that will set quickly will serve. But, if making the gelatine reliefs is meant, then one of a different character must be used. The "Amber" gelatine of Messrs. Nelson, Dale, & Co., is the one most generally employed for that purpose.

R. J.—The mere fact that the photograph bears the word "copyright" on the imprint is no proof that there is a legal copyright in the picture, or even that it has been registered at Stationers' Hall. However, it is illegal to attach the word copyright to a photograph that has not been registered, as it is misleading. It must be borne in mind that a photograph may be registered and yet not be legally copyright if the matter were tested in a court of law.

G. A. H. writes as follows: "I have been told that if a diamond cut is made in a piece of glass, and the glass is not separated at once, the cut will heal up, so that after a few days the glass cannot be divided where the cut was made. Will you kindly tell me if this is a fact?"—We have more than once heard the same thing asserted, but have never put it to the test of experiment. The thing is easily tried—perhaps our correspondent will make the experiment and let us know the result. Possibly others will like to try it.

R. TAYLOR asks how mirrors which are fixed at an angle of 45° in front of the lens for taking reversed negatives are made, and whether thick plate glass or patent plate is best, and whether the glass is silvered on the back or the front, and how?—Commercial plate, or patent plate, glass is not reliable for the purpose. The glass should be optically worked, so that it has an absolutely plane surface. Unless this is the case, anything like perfect definition will be impossible. The glass is silvered on the surface that is the one nearest the lens. Formulæ for silvering the glass will be found in any of our ALMANACS.

J. C. P. has a very old photograph to copy which is much tarnished, and wishes to know how to clean it and restore it as far as possible before copying. It is on zinc or some similar metal. He tried one lately that was very much tarnished, and as soon as he placed it in a tray of clean water to soak the whole of the film broke up. However, it was very frail when he received it. This one seems all right on that score, but he is afraid of it after his experience with the other.—From our correspondent's description of the picture we are unable to identify it. If he will send it for our inspection, we shall probably be able to assist him.

S. MOORE, who says he is a novice—and we have no reason to doubt him—sends us several negatives for advice thereon. They are marked, have large transparent holes in them, and are covered with mottled stains. He asks if the defects are due to the plates or to his work.—The latter decidedly. The marks are due to the plates not being covered with the developer when first immersed in the solution. The cause of the spots is air-bubbles adhering to the film while in the developer. The mottled stains arise from the dish not being kept in motion while the development is proceeding. The various causes of trouble being indicated, the remedy is obvious.

WEST LONDON PHOTOGRAPHIC SOCIETY.—June 11, Watford. Cycling division meets School of Arts, 2.30 p.m. Tea at "Essex Arms."

WE have received the summer supplement to Vevers' catalogue, which embodies in a handy form particulars of new apparatus and sundries.

NORTH LONDON PHOTOGRAPHIC SOCIETY.—At the next meeting of this Society Mr. J. Traill Taylor will discourse on *Lenses Ancient and Modern.*

LONDON AND PROVINCIAL PHOTOGRAPHIC ASSOCIATION.—June 16, *Some Prime Factors in Exposing*, Mr. Howard Farmer. 23, Annual General Meeting.

THE PHOTOGRAPHIC CLUB.—June 15, *Platinotype Possibilities.* 22, *The Relative Permanency of Prints by the Various Methods in Present Use.* Outing, Saturday next (18th), Burnham Beeches. Train from Paddington at twenty minutes past two.

MESSRS. B. J. EDWARDS & Co. inform us that they are being repeatedly called on to furnish instructions for dissolving one ounce of eikonogen in thirteen ounces of water, that being the proportion given on page 800 of the 1892 ALMANAC as their formula for eikonogen developer. We regret the printer's error. The correct formula is as follows:—Eikonogen developer, for isochromatic plates: No. 1. Distilled water, thirty-five ounces; sulphite of soda, two ounces; eikonogen, one ounce. No. 2. Distilled water, ten ounces; carbonate of potash, one ounce. For use, mix one part of No. 2 with three parts of No. 1, and (when new) add to each ounce of the mixture two to three drops of a ten per cent. solution of bromide of potass. The developer can be used repeatedly by adding more No. 1 and 2, omitting the bromide.

JOURNAL OF PHOTOGRAPHY.

No. 1676. Vol. XXXIX.—JUNE 17, 1892.

DUST.

One of the most fatal enemies to good and clean photography is dust in one or other of the many protean and often unexpected forms in which it presents itself in photographic practice. It will not be time ill spent to take into consideration some of these cases, their prevention and cure. We naturally first turn our thoughts to the apparatus employed, first, of course, being the lenses. Old readers of this Journal do not need to be reminded of the number of times we have pointed out how necessary it is, first, to protect all lenses from dust; and, secondly, to use great care in removing it when after all precautions it has gradually settled upon the glass surfaces. For field work, when the camera is only occasionally employed, it will often be found necessary to remove a slight film before use, yet this necessity might in the main be obviated if the instrument were provided with two caps instead of one. It may be supposed that the reason why two such protections are not provided by the maker is the extra price that would have to be put upon the instrument—an important consideration in these days of competition and low prices. It should be remembered that dust will find its way into almost every case, drawer, box, or other receptacle used for containing lenses, while the universal velvet-lined cap is an almost perfect protection. There is something to be said in favour of the old metal caps, formerly the only kind employed, for they fitted dust-tight against the lens. When the lens is a practically complete fixture to the camera, as in studio work, covered and uncovered by an internal shutter, it is often customary to leave it unprotected, and occasionally to wipe its surface, but such treatment of a valuable instrument is as unwise as unfair to the maker; it should always be capped when not in use, although there be a complete closing and unclosing arrangement inside the camera. When lenses are put away they should, further, be always dusted with a soft camel's-hair brush to remove any particles that may have become attached while they have been in use, for "dust" being of very varied constitution there may, possibly, be some adherent spot capable of acting as a nucleus to collect other injurious particles not easily removed, or that would scratch the surface during removal.

All lenses, moreover, will need occasional (but only occasional, when ordinary care is used) unscrewing and internal cleaning, owing to the deposition of particles of dust, so fine as to partake more of the character of a stain than a collection of small particles. If this film, for such only can it be called, be not removed, it will be found that under some conditions of light it will mar the crispness of the shadows, and tend to flatness of image. The fact is, this film becomes actually illuminated in a strong light, and so gives off rays which reach the whole plate; if a bright light shine on the lens, and a badly illuminated object be photographed, the effect is sure to be brought about.

Now, as to the removal of these film-like deposits, as well as more grossly visible particles. The only secret in practice is first to remove the loosely adherent particles by means of a brush, and then to polish the surface. For this latter purpose nothing but the softest possible material should be used, some preferring washleather, others an old linen cloth. If the former be chosen, it must first be well washed, to remove the lime dressing, and also be occasionally washed afterwards, to remove any possible gritty particles that it may have collected, and which, being unseen, might injure many surfaces before being discovered. On this account alone there is much in favour of the contention of those who say that nothing but old linen should be used, and that, after employment a few times, it should be discarded, and replaced by a new one, which would be readily done, as the cost is *nil*.

On no account whatever should rouge putty powder or other polishing material be used, except by an expert, for he only knows when it is of the right kind or how to use it. A lens, when sent out from the workshop of a good maker, has a surface of exquisite polish, which can easily be injured, and the loss of which is so much off the value, commercial and practical, of the instrument. If any one examine hap-hazard a dozen lenses belonging to amateurs of average carefulness, and that have been in use a few years, it will be surprising if he do not find more than one having hair scratches on its surface, not always producing perceptible ill effects, but capable on occasion of doing great harm. We have seen a lens with a circular scratch, caused by polishing with a dirty cloth, and many a lens with a deep and decided cut, from similar causes.

We may here add a word of advice about the treatment of such marks. Often they are no detriment to the performance of the instrument, but under a certain conjunction of circumstances they may totally ruin a negative, as, for example, when a very strong light impinges upon the lens from a bright window on one side, when photographing a dimly lighted interior, the scratch may disseminate more light than the view itself. The remedy, therefore, is to paint the scratch with black varnish; the image will not be in any way interfered with, the light will only be reduced a fraction of one per cent., and, in all practical respects, the lens will be equal to new. The importance of this particular branch of our subject has led to our occupying so much space over it that other ramifications of the "dust" question must remain for treatment in a succeeding number.

THE FIXATION OF GELATINE PRINTS.

In writing on the subject of *The Fixation of Prints* in last week's issue, we dealt principally, if not solely, with prints upon albumenised paper; and, though the same general rules prevail in both cases, still prints or negatives on gelatine films present some points which require somewhat different treatment. The comparatively greater thickness, for instance, of the gelatine film renders necessary not only a longer action of the fixing solution in removing the silver salt, but also a correspondingly longer washing to eliminate the soluble production of its action. Then, again, the physical character of the two films is utterly different, the albumen being hard, insoluble, and capable of withstanding a considerable amount of rough usage, owing to its coagulation in the silver bath, while the gelatine is tender and usually soluble in warm solutions, and, even when "alumed," it requires careful treatment to avoid damage.

These physical differences may at first sight perhaps not appear to amount to much, or to be of very great importance; but, in practice, the contrary will certainly be found to be the case, as we shall show. But there is a chemical difference which possibly has far greater effect on the absolute permanency or otherwise of images in albumen and gelatine respectively. *Pure* albumen contains, as one of its constituents, a portion of sulphur, amounting, according to one analysis, to nearly two per cent. of the whole, a considerable proportion, truly, in a chemical sense; but, in ordinary egg albumen, the form in which it is used in the preparation of photographic paper, the proportion is much greater even when fresh, and still further increases as the albumen becomes stale or putrid. As it is the practice of some albumenisers to intentionally keep the albumen until it has arrived at a certain degree of putrefaction, in order to thereby attain a higher gloss on the paper, it will be seen that the chances are greatly in favour of the marketable film being particularly rich in sulphur, or sulphur compounds, long before it comes in contact with the fixing agent.

In the composition of pure gelatine, on the other hand, sulphur is practically absent, or nearly so, though some chemists have indicated small quantities, while others have altogether failed to detect its presence. In the commercial article, it is true that that sulphur may exist in very appreciable proportions, owing to carelessness in manufacture, sulphurous acid being employed in various stages of the process to decolourise the preparation. Still, while this is little likely to occur with the samples now specially prepared for photographic purposes, and used almost universally by the manufacturers of gelatine films and papers, it may be said that the form in which the sulphur presents itself is far less dangerous than in the case of albumen, being rather in the form of sulphite or sulphate than free or in the form of sulphide, as in the albumen film.

Sulphur or sulphur compounds are formed and given off by the decomposition of gelatine, as of albumen or any other organic matter; but this phase of the question, so far as gelatine is concerned, need scarcely trouble the photographer, since the slightest approach to decomposition or putrefaction entirely ruins it for the purposes for which it is employed. Pure, fresh gelatine is an essential to the manufacturers, and no inducement exists, but quite the contrary, to allow it to become in the slightest degree stale.

The effect of this chemical difference amounts just to this, that, whereas albumen paper may contain within itself all the essentials for the formation of dangerous sulphur compounds before, during, and after sensitising, and even after "perfect" fixation and washing, gelatine starts with no such evil character necessarily attached to it, and with careful treatment in the matter of fixing and washing appears to promise a prospect of as complete permanency as can be attained in an image composed of silver. The question, then, is simply what are the best means to be taken to ensure perfect fixation and washing?

In the opening lines of this article we mentioned gelatine negatives, and though these are far less likely to suffer from, at any rate, insufficient fixing than any positives, merely because they are usually treated singly and individually, still all who have had any experience in negative work will know how frequently they do actually suffer from that cause. Take glass negatives, for instance, with which the ocular test of perfect fixation would appear to be all that was required, and go back to the old days of, say, ten years ago, before the introduction of plate-coating machinery, and when films were not so uniform even as nowadays, how often was there found along one edge or on one corner of a plate an unsightly brown stain which gradually developed and intensified itself in course of time, although entirely absent when the negative was freshly made. This was due solely to the imperfect action of the hypo on the thicker portion of the gelatine, where, although all the silver bromide might have been dissolved, *i.e.*, converted into the double hyposulphite of soda and silver, and the film thus rendered transparent, the process had not been carried far enough to produce the perfectly soluble form of the double salt; consequently, no amount of after-washing would remove the evil, or, in much the same way, washing that was sufficient for the thinner parts of the uneven film would still leave sufficient of the soluble double salt in the thick portions to bring about the same kind of discolouration as time went on.

Now, when the difficulty of judging the completeness of the fixation of a film on a transparent medium like glass is so great, how much greater still must it be when the support is opaque paper. The paper prepared by the larger manufacturing firms in long rolls is less liable to suffer from inequality of coating, but that prepared in single sheets is still, it is to be feared, liable to the charge. The ocular test is useless, and as we showed last week the chemical ones are troublesome and inefficient, so what is to be done?

The only general system we can propose is to ascertain what time of immersion is required in a bath of certain strength and at a certain temperature, and in practice to invariably adhere to those conditions, or preferably to give a considerably longer immersion, using always, as a matter of course, a fresh and clean solution of hypo. After that, the question is reduced to one of sufficiency of washing, and this can be attained by the expenditure of a little care. Owing to the greater thickness of the gelatine film, it will be necessarily more protracted than with albumen, but it may be hastened, as may indeed the operation of fixing, by separately "squeegeeing" at intervals each print or negative face downwards on a sheet of glass or ebonite, so as to mechanically force out of the pores of gelatine and paper as much of the solution they contain as possible. On reimmersion in fresh water, the pores will be refilled, and the remaining salts thus far more rapidly diluted and eliminated than is possible by mere soaking.

Another good plan, though involving a little trouble, mentioned to us many years ago by Mr. John Stuart, of Glasgow, consists in giving the print or negative a thorough washing and

then drying. Any salts that remain will now be in the form of crystals and the gelatine in a state to readily and quickly absorb water. The print is therefore reimmersed in fresh water for a short time when, any remaining hyposulphites will be found to have completely disappeared.

ORTHOCHROMATIC PHOTOGRAPHY.

DR. ACWORTH'S paper on this subject, read at the meeting of the Photographic Society of Great Britain on Tuesday last (see page 394), was to some extent devoted to negativing the belief that an ammoniacal solution of a dye was necessary in order to effect the sensitiveness of an emulsion to certain rays. In this he quoted the experience of several able experimentalists, and was supported in his views by some of those who took part in the subsequent discussion.

But there were other points of interest in the paper quite outside this one. Perhaps the principal of these was the statement that, contrary to what might have been supposed, a very minute trace of erythrosine in combination with silver nitrate not only sensitises for the yellow rays, but also causes all the other regions of the less refrangible end to become more sensitive.

The experiments he describes not only bear out this important feature, but also bring to light others of great comparative and particular interest. To three separate emulsions, each of 30 c.c., and containing half a gramme of erythrosine, he added, in one case, nothing; and in the other two half a gramme of silver nitrate and 5 c.c. of ammonia, respectively. The emulsion containing erythrosine alone showed "a small band of yellow sensitiveness;" that containing the erythroside of silver, eight to ten times greater sensitiveness to yellow, as well as increased sensitiveness through the green to the blue. The effect of the ammonia on the third emulsion was practically *nil*.

In the foregoing experiments the silver and the ammonia were added to emulsions already containing erythrosine, but in a fourth experiment the erythroside of silver itself (·010 erythrosine and sufficient nitrate to form the erythroside) was added to the emulsion, and the maximum effect in the yellow obtained. Dr. Acworth concludes from this that large quantities of dye are superfluous, and states that the maximum effect may be obtained by using as little as one or even half a milligramme of, erythrosine to 30 c.c. of emulsion, if the dye be perfectly associated with the silver.

While there has been a tolerably common idea that in orthochromatic emulsion making the quantity of dye necessary was much larger than Dr. Acworth indicates, experimentalists in orthochromatic bathing have been well aware that the quantity required is there exceedingly small. In the course of the discussion, Captain Abney again described his own method of procedure of flooding the plate with the erythrosine solution, and washing out as much as possible of the dye, so that the plate could hardly be distinguished from an ordinary plate. Under this treatment, the quantity of dye which remains in a plate must be infinitesimal.

Several other matters of considerable interest to experimentalists in orthochromatic work and others cropped up in th course of the paper and the discussion, to which we refer them for further details. Dr. Acworth's success in sensitising for all rays of the spectrum by means of tincture of jaborandi and silver nitrate, gives promise, we hope, of further advances in orthochromatic work.

The Convention.—We are authorised to state that the Lord Provost of Edinburgh will officially receive the members of the Photographic Convention of the United Kingdom on July 11. This action on the part of the municipal chief of the modern Athens will, we are confident, be viewed by the members of the Convention with the liveliest satisfaction.

A Large Group.—A photograph of the seventh International Congress of Hygiene and Demography, held in London last August, embracing over 1000 ladies and gentlemen, has been published by Messrs. Barraud. In order to provide sufficient standing room for the representative company figuring in the picture, the proportions of the great staircase of the University of London, which furnishes the background, were enlarged. Each member of the Congress was given a separate sitting, and a satisfactory likeness was forthcoming in each case, and the combination of this large number of portraits is said to have been very successful.

An Automatic Photograph Company Pays a Dividend.—The Automatic Photograph (Foreign and Colonial) Company, Limited, was, we believe, wound up not long ago; but the failure does not, after all, appear to have been a very bad one, inasmuch as we observe that a first and final dividend of twenty shillings in the pound has just been declared, and is payable by the Official Receiver and Liquidator. This means, according to our limited acquaintance with the niceties of company finance, that the shareholders get a return of their capital. Penny-in-the-slot photography, we learn, is still in existence along "the shores that round our coasts from Deal to Ramsgate span."

Recovering Gold and Silver with Aluminium.—Mr. J. R. Clemons, of Philadelphia, whose method of toning with aluminium chloride was referred to in these pages a few weeks ago, suggests the recovery of gold and silver from old gold and silver solutions with the same reagent. The bath is first acidified with hydrochloric acid, and a strip of aluminium placed in it. The gold is said to be precipitated in a good state of purity, and needs only to be slightly washed before being reconverted into the state of trichloride in the usual way. The plan also answers for combined toning and fixing baths, the silver being separated from the precipitate with nitric acid, and the sulphur filtered off from the redissolved gold. Metallic silver is precipitated from the chloride in a similar way.

Ammonia Poisoning.—An inquest was held the other week at Portsmouth on the body of a blacksmith, who had committed suicide by drinking ammonia. According to medical testimony, one teaspoonful of that alkali had been known to destroy life. The coroner asked if it was not unusual to sell poison in such "large quantities," and, on being informed that ammonia was not included in the Sale of Poisons Act, remarked that that was rather strange. There are, besides ammonia, several other chemicals employed in photography of a highly poisonous nature which are not included in the Act, and that are sold in much "larger quantities" than one tablespoonful at a time, but of the poisonous nature of which their users are, as a rule, ignorant. There is, as it were, a fashion in poisons, cyanide being in favour among photographers.

The Kinnear Camera.—We this week publish in our correspondence columns a letter from a gentleman whose name is assured of perpetuation so long as the camera is in existence—we allude to Mr. Kinnear, the inventor of the form of camera which is called after him. Mr. Kinnear, *àpropos* of patentable improvements, sarcastically remarks that "it seems now as if any new screw or slot introduced into a camera was worth patenting." He goes on to wonder what his income would have been now if he had patented the Kinnear camera, which he invented in 1857, and which, with subsequent improvements, is in all essentials the camera now made by hundreds of thousands. Mr. Kinnear is one of the leading architects of the present day in Edinburgh, and architecture is his debtor as well as photography.

A Line to be Drawn.—Mr. Leon Vidal, in the current number of the *Moniteur*, thinks that photographic associations should consist of two distinct groups, the one formed of experimentalists and *savants* devoted to the study of the progress and applications of photography; the other, of amateurs properly so called, whose ambitions do not rise above the sportive use of the hand camera. Between the latter and such men as Janssen, Marey, Lippmann, the Henrys, Lumière, Braun, Balagny, and others, there is, as M. Vidal infers, a tremendous gulf, of which, however, we can supply a perfect parallel on this side of the Channel. Sportive photography, he thinks, should be kept within its own boundaries, and he complains that it is scarcely respectful to scientific and industrial photography for such a beautiful branch of human knowledge to be degraded by certain photo-mural decorations of Paris which he describes. He winds up his remarks on the subject by reiterating the necessity of separately grouping earnest and ephemeral photographers in societies and exhibitions.

World's Congress Auxiliary of Photographers.—The preliminary address of the Committee of the World's Congress Auxiliary on a Congress of Photographers says: "Among the Congresses of the Columbian Exposition of 1893, that devoted to photography should rank high, and be, as it undoubtedly will, a permanent benefit to the civilised nations of the earth. The advancement that has been made in photography, and the processes dependent upon it, within the last twenty years has astonished the artists and scientists of the world. By its aid the astronomer has discovered countless stars and remodelled the map of the starry heavens. It is extensively used in almost every department of art, literature, and science. Its future possibilities are too great for any one to estimate. It is the design of the Committee to have men and women, who have become distinguished in the various departments of the photographic art, and the processes dependent upon it, deliver papers before the photographic congresses which shall contain their best thought, and, after well-regulated discussions, shall become the property of the World's Congress Auxiliary, and, if deemed worthy, be published in the Encyclopædia of proceedings." A lengthy list of subjects to engage the attention of the Congress is then given, and the assistance of photographic societies is asked, as well as suggestions from individuals. A committee is in charge of the arrangements, and "advisory councils" have been appointed both in America and other parts of the world. The Chairman of the Committee is Mr. J. B. Bradwell, of Chicago, U.S.A.

ON THINGS IN GENERAL.

I DO not know whether my readers are most to be congratulated upon escaping, for the first time for twenty years, my monthly visitation, or myself upon being able to resume my pen after an enforced holiday. When, as in my case, one's medical adviser emphatically forbids either reading or writing, inclination must go to the wall. However, I trust my weapon is not rusted by disuse, and that it is as capable as ever of the friendly pricking it is ever intended to give.

Of matters that have been discussed since my last, I have been much interested in the old, old question of amateur *versus* professional. As I need not inform the bulk of the readers of this JOURNAL, an amateur in athletic circles is one who does not compete for a money prize against any one, nor for a prize of any sort against a recognised "professional." He obtains certain advantages by these conditions, and is content to abide by them. But in photography an amateur appears to be one who may make as great an income as he likes by exercising his profession, so long as he has not an office or reception-room devoted to the purpose. Quite recently I heard of a case of an amateur who received 150*l.* for a set of negatives taken in this country, and who yet would deem it an insult to be called a professional photographer. But I do not suppose he ever paid income-tax upon the money. Personally, I do not see, in a free-trade country, why a man should not add to his income in this manner; but I should object to his gaining a medal as an amateur, and still more to his entering the establishment of a professional rival under his false colours, and so gaining information calculated to be of benefit to him in his commercial pursuit of the art. I expect the other day, at the London and Provincial Photographic Association, Mr. Haddon was having a sly laugh at the expense of some of the narrow-minded professionals when he suggested to amateurs their return to wet-plate work as a means of pacifying the former. If the amateur, so called, can make money, let him do so, and forfeit any advantage his amateur status brings him. The good amateurs will, and often do, become good professionals in many cases, and all the better for the profession, which cannot be supposed to exist for the purpose of giving a monopolising status to a lot of indifferent workers, who might be better employed otherwise.

The introduction of the concentric lens promises to mark an epoch in lens production. The controversy which it has raised is only what might be expected, for, when such highly technical questions as the manufacture of lenses is introduced, there is generally some wild talking, the subject being one upon which so very few are competent to give an opinion worth listening to. I have been, I may say, anxiously looking forward to the ultimate publication of the new lens, for, when I had the privilege of being shown in Messrs. Ross's private laboratory, some years ago, the first of the type made, but which they were doubtful about repeating till they had further investigated the keeping qualities of the glass of which it was constructed, I foresaw a great future for the instrument. By the bye, the account given in the *précis* of the proceedings at the Photographic Society of Great Britain is a little indistinct. A "bulb" is there referred to, which to outsiders will appear a mystification; it is simply an achromatic lens in the form of a bulb or sphere which, as explained, is used in examining the image given by a lens. No ground glass is employed as the "bulb" does the same work, but with far greater accuracy. Those, however, who wish to adopt some such means in their own practice can with advantage use one of the pocket achromatic magnifiers now so common. I refer to the kind that appear like a Coddington lens without the diaphragm. If mounted on an adjustable stand, they answer excellently for examining the image given by a photographic lens.

It is unfortunate that the term "depth of focus" has become a subject of discussion, seeing that a true focus lies at a point only, and can have no depth, which, if it be confused with depth of definition, the latter expression lends itself to a vagueness of interpretation far too inexact to found a scientific argument upon.

Another important event on the optical side of photography is the introduction of the tele-photographic lens, which in a limited sphere is capable of considerable use. But it must not be forgotten that, quite apart from any question of difficulty of avoiding vibration, and of getting rid of the effect of haziness through uneven transparency of the atmosphere, there will ever be the effect of haze in the atmosphere to battle against. How many negatives are there in the country at this moment out of the tens of thousands annually produced in which objects half, nay, a quarter of, a mile distant can be compared for clearness and transparency of shadows with those fifty or one hundred yards away? For scientific purposes and as objects of reference, photographs of distant objects may by the aid of the new lens be taken so as to be most valuable, but, as to pictures, scarcely ever. What is "atmosphere" in a picture, but the toning down of the darks by the aid of the haze? it is capable of beautiful effects in pictures where it forms part of a whole, but, when the parts are viewed divested of the surroundings of foreground, &c., they make a poor display.

I have been rather sorry to see the eager way in which, so far as an outsider can judge, a trap has been attempted to be set for Mr. Lyonel Clark in the matter of completion of fixation of prints. Apart from the merits of the case itself, he has conclusively shown that he is in no way responsible for the question set by the examiners.

What an amusing batch of letters the Editor must have when there lies before him the week's queries; but, of all the droll questions asked, surely the drollest is whether, when a piece of glass is cut by a diamond, the cut will fill up and "heal" gradually if left to itself? If the question had been of wax, pitch, or similar liquids, there might be reason for it; but glass!

I see some one has been writing about the removal of silver stains upon negatives by immersing them in a body containing, among other things, twenty per cent. of nitric acid. Might I recommend that, if that be tried and with nonsuccess, the experimenter ascertained

whether boiling them in a pan of water for half an hour would produce any more satisfactory result? I should not think it would be any less dangerous to the integrity of the image.

FREE LANCE.

OBSOLETE PROCESSES.

No. 4.—THE ALBUMEN PROCESS.

THE albumen is the oldest of all glass processes. It cannot altogether be classed as obsolete, inasmuch as it is, in a modified form, still used to some extent for stereoscopic and lantern transparencies. In this form, however, it differs materially from the process by which negatives used to be obtained, and that is the one that will now be described. As in the collodion process, so in the old albumen one, great care had to be bestowed on cleaning the glass, so as to get it chemically clean. The details of this work need not be gone into in this article.

It may be well to explain here that, in the earlier days of this process, there were two methods of iodising the albumen. One was by first coating the glass with plain white of egg, and then submitting the dried film to the vapour of iodine, in the same manner as a Daguerreotype plate was iodised. The other plan, and the one universally followed in the later days, was to dissolve an iodide in the albumen before it was applied to the glass. It is easy to conceive how the former method suggested itself when it is considered that, at that period, the Daguerreotype was the process of the day. Here is a formula that was in very general use, though, as in most of the older processes—and many modern ones too, for that matter—different workers had pet formulas of their own. Albumen from fresh eggs, ten ounces; iodide of ammonium sixty grains; and bromide of ammonium five grains, dissolved in an ounce of water. The mixture was then beaten into a stiff froth, either with a silver or wooden fork, until the vessel containing it could be inverted without any fluid running out. The prepared albumen was then allowed to remain undisturbed in a cool place until the following day. By that time a large proportion of the albumen had subsided, and was then carefully decanted, the almost solid crust of froth on the top acting as a filter as it forced its way through.

For coating the plate it was attached to a holder. This usually consisted of a short wooden rod, at one end of which was a lump, or a cup-shaped piece, of gutta percha. This was warmed in the flame of a spirit lamp, until the outer surface became soft and adhesive. It was then pressed on the back of the glass, to which it adhered. Some of the albumen was then poured on the plate and guided over the surface with a glass rod or a strip of paper. After the albumen had been flowed once over the glass, it was slightly drained off. Then a rotary motion was imparted to the plate by twirling the rod of the holder between the fingers, so that the slight centrifugal force caused an even distribution of the coating. An even film having been thus secured, it was necessary, in order to retain it, to keep the plates in a perfectly horizontal position till they were dry, for albumen, unlike gelatine, has no "setting" properties. For this purpose drying boxes were sold. These were wooden boxes mounted on levelling screws, and having horizontal grooves in them, like an ordinary plate box set on end. In these grooves the plates, immediately they were coated, were placed, alternately with a thin board of porous wood that had previously been made very dry, to absorb the moisture. One of the chief difficulties in connexion with this operation was that of preventing dust from reaching the film, which always seemed to have the greatest affinity for it, any particles of which would show as spots or comets in the finished negative. At that period, it may be mentioned, the most absurd statements were made as to the precautions taken by some workers for its avoidance. The plates, at this stage, if preserved dry, would keep good for years.

The plates were sensitised in an aceto-nitrate bath, similar to that used for wax paper, but stronger, namely, fifty grains of nitrate of silver and a dram of acetic acid to the ounce of distilled water. The sensitising was usually done in a flat dish, and the time of immersion was very brief, from thirty to fifty seconds only being allowed. By use this bath becomes discoloured, like that used for sensitising paper, and it was decolourised in the same way, namely, with kaolin. After the plates were taken from the bath, they were well washed in distilled water to remove all the free silver, and dried. As the film of albumen was very thin, the plate dried quickly. When dry, they had a thin, pale blue opalescent appearance, quite different from the modern dry plate. Albumen plates in the sensitive state possessed excellent keeping properties, both before and after exposure. Indeed, they have been kept for years, and then yielded good pictures.

With regard to the exposure, this was the slowest of all processes on glass. With a single lens, possessing an aperture of *f*-30, in a fairly good light, an exposure to a landscape might be reckoned at from seven to twenty minutes. Great latitude was allowable in this process, perhaps greater than in any other, the gelatine not excepted.

The development was also a slow operation. The time usually was from a quarter to three-quarters of an hour. In the case of great under-exposure, several hours were often required. The developer was a saturated solution of gallic acid, to which a drop or two of the aceto-nitrate bath had been added. In the later days of the process, pyrogallic acid, restrained with acetic acid, was used by some, but gallic acid was originally the universal developer for albumen plates. If the negative was under-exposed, the energy of the developer could be much increased by using it warm, and even hot; or heat might be applied locally, and by that means detail in deep shadows, which would otherwise be lost, could be forced out. We have frequently had recourse to a heated soldering iron, or even a poker, applied to the back of the plate to coax out detail in the heavy shadows when the negative has been much under-exposed. We have even seen the flame of a spirit lamp applied. Sometimes during the development—particularly if it were a long one—marbled stains would make their appearance. These could, however, be cleaned off with a pledget of cotton wool under the tap, and the development continued. The fixing was done with a solution of hyposulphite of soda; two ounces of the salt in a pint of water.

One very general fault with albumenised negatives made by novices was the hard and "chalky" prints they yielded. This was not attributable to the process, but to the manipulations, the negatives being made too dense. The image of an albumen negative developed with gallic acid was generally of a dirty olive-green tint, and of a highly non-actinic character; hence it obstructed far more light than, from its density, it might be judged it would.

That the albumen process was, and is, equal to yielding the finest results, is proved by the early work of such men as Ross and Thompson, of Edinburgh; McPherson, of Rome (very large sizes); Ferrier, and others. Indeed, the albumen process will yet hold its own, except for speed, against any that has hitherto been introduced.

It has been mentioned that this process is an exceedingly slow one—that refers to the normal method of working; but it is on record that one of the most rapid pictures yet taken, including those with gelatine, was that made by the late Fox Talbot, when he, in 1851, at the Royal Institution, took sharply printed matter pasted on a rapidly revolving wheel by the light from the discharge of a Leyden battery.

THE CAMERA AND THE CONVENTION; OR, PICTURESQUE SCOTLAND AND PHOTOGRAPHY.

VII.

AT the last Glasgow Convention, one of the Clyde trips was down to Tarbert and back in the *Columba*. It was most enjoyable, but the distance was so great that most of the places could only be glanced at in passing, with the exception of Tarbert, where we landed and the Convention group was taken. Most of the photography that was done that day was taking shots at each other on board the boat, for we were sailing pretty well all the time from morning till night. Certainly, a few very fine instantaneous effects were secured at some of the quays where we put in. Notable amongst these was Mr. Seaman's picture of the Rothesay Pier; it was a gem, so clear and fully exposed, in spite of the shortness of time and the hundreds of moving figures.

THE GARE LOCH.

On the north side of the Clyde, after passing Bowling and Dumbarton, which we have previously noted, we come to Helensburgh, which is the nearest town to the Gare Loch. The Gare Loch is the first of

these inlets of the river, that stretch away miles between the hills, and are familiarly termed lochs. This inlet runs up north-west about six miles, and its banks all round are well wooded, and rich in pictures. Leaving Helensburgh, and going up the loch, we pass Row Sandon—the village at the head of the loch—and coming down the other side, at the point opposite Row, we come to Roseneath, a very beautiful spot. This would embrace a good day's photography. From this point, a walk across the hill would bring you to Killcreggan. All along these fringes of the sea the prospect is charming, and at any point pleasing effects are to be obtained. There is a pier at Killcreggan, and, further on, one also at Cove, where the next loch enters, between Cove on this, and Blairmore on the other side. This is Loch Long, and Loch Goil strikes out from it some three miles up.

During the summer months, daily tours are arranged for in this vicinity, embracing the finest stretches of river, rock, glen, and mountain passes. One favourite run of this kind is by boat to Loch Goil, where a coach awaits its arrival to convey passengers through "Hells Glen" to St. Catherine's, on the shore of Loch Fyne. Here there is a ferry boat to take passengers across to Inverary, where the *Lord of the Isles* lies waiting to bring the passengers home, by the Kyles of Bute, to Princes Pier, Greenock, or any other calling port more convenient.

Another trip of the same kind is by coach from Dunoon to Loch Eck, thence to Strachur, where a boat waits to take passengers to Inverary.

In this case, also, the journey home is by the *Lord of the Isles*. Leaving in the morning by the *Lord of the Isles* for Inverary, the same ground can be covered the reverse way.

Loch Striven.

We once drove across the hills from Kirn to Loch Striven. We did not find it up to our expectations from a photographic point of view. After leaving the shores of the Clyde, and until we neared the loch at the other end, the hills were barren and bare, and lacking in photographic subject, although, leaving photography out, and looking at them from a picturesque point of view, they were very grand. Hills upon hills, nothing but hills ranging for miles, standing up in all their majesty, without a sound to break the silence, save the bleating of the sheep, that, away in the distance, looked like white pebbles on the surface of the hill.

Away, buried in these hills, we came upon a charming bit in the way of an old dry stone-built, thatch-roofed cottage, of which we made a picture, and at the door we placed the old woman that belonged to it, an old soul that looked as worn and antiquated as the house itself. In conversation she told us that she had been born there, married there, reared her family there, now they were all married and away, and she was still there herself, and not a doctor within call for eight miles. Fancy! and she looked contented and happy.

Rothesay.

Passing Innellan and Toward Point, the Isle of Bute lies before us. Crossing the bay, we reach Rothesay, which is really the most popularised resort on the Clyde, and if esplanades, and bands, and good shops, and a never-ceasing influx of visitors are the sure indications of the well-doing of a place, then Rothesay certainly does well. It lies in the very midst of some of the finest Clyde scenery, and possesses on its own shores places of beauty and interest, combining picturesque drives, lovely walks, and enjoyable sails, all of which commend it as a good centre for the tourist who has a little time to spare. Rothesay, as a town, looks very picturesque from the bay. The ruins of Rothesay Castle are worth the attention of the photographic visitor.

Wagonettes ply daily to Mount Stuart, the seat of the Marquis of Bute. The grounds are open at all times. They are filled with good things, from a photographic point of view, especially the walks and avenues, they are so beautifully wooded. On the way to Mount Stuart you pass Ascog, where Montague Stanley is buried.

Kyles of Bute.

The tram car can now be had from the town to Port Bannatyne, which is the beginning of the Kyles. Opposite Port Bannatyne Loch Striven strikes out from the Kyles, finding its way some eight miles north between the hills.

The Kyles of Bute is that belt of sea that winds round the northern half of Bute, covering a run of some seventeen miles, and it is certainly one of the finest water effects on the Clyde. All the way to Loch Fyne there is a constant shifting of beautiful scenes, twining and turning out and in between between shore peaks and islands, leaving on the imagination of the beholder that surely now he is going to be land locked, and this sensation repeats itself every little bit of the way. With the shores now close in, and now at a distance, with villages, clachans, and cottages springing into view in a most bewildering fashion, and always charming, the steamer goes churning on its way until we reach the open waters at Loch Fyne, after having passed Tighnabruich and other points of interest on the way. Tarbert, on Lock Fyne, is a good place for fishing boats and effects. We have seen many artistic pictures that have been taken there, but one has to wait for them, a short time like that we had at the Convention gives no opportunity for such pictures. Tarbert is much affected by seascape artists.

The next stopping-place is Ardrishaig. If you were staying here any time, some pictures could be got of the Crenan Canal, which is quite near to the landing-stage at Ardrishaig.

Inverary and the Clyde.

Inverary, on Loch Fyne, is also a good centre for a few outings. At this place is the seat of the Duke of Argyle. The town is most romantically situated, and endowed with charming surroundings, and in summer it is also quite interlaced with steamer and coach routes, covering the ground in all directions, one or two only of which we have previously noted.

The islands, such as the big and little Cumbraes, are not so picturesque as many other parts of the Clyde; but Arran is a spot where some time could be profitably spent.

The yachting on the Clyde is one of the features of the place that will commend itself to all lovers of this class of work. A better place than the waters of the Clyde for boat or yacht photography it would be impossible to get. At almost any of the quays on the river good positions for this class of work will be found. Hunter's Quay, however, is probably as good a place as any for a day's work on yachts. The headquarters of the Clyde Yacht Club are there, and a greater gathering of the white-winged sails are often to be found at this spot. Many will remember the day we had *yacht shooting* on board of our own steamer (hired for the day) during the Glasgow Convention time, when, during the bright part of the day, we kept running in and out amongst the graceful racers, with the famous *Thistle* in their midst. That really was a proper method to procure impressions of sailing ships, as the hundreds of plates exposed and the many successful productions proved.

Now, we will have to think of going home, as our plates are done and we have to develop many impressions. Oh, yes, we could take you further afield, and find no end of beautiful districts and places that would delight the heart of the landscape worker. It will be better to leave them for some other time, when the programme now set before us has at least been partially exhausted, and a little opening made for something new. Then we may tell of pastures yet unexplored.

May the Convention gathering have good weather and good times!

PICTORIAL SELECTION IN PHOTOGRAPHY.*

Breadth.

Remember that simplicity of construction, combined with masses of light and shade, agreeably disposed, are the requisites necessary to give a picture dignity and repose. Therefore, although it is most desirable to have variety and contrast in the lines of your composition, it is highly important that these values be carried to no great excess. An outline, well diversified in a natural manner, will always be more pleasing to the eye than a repetition of lines without variety; for the sight is as soon fatigued with monotony and repetition of forms as the ear is with the continued recurrence of the same sounds. The rounded forms of the clouds will contrast with the angular forms of the mountain, and these, in their turn, with the horizontal lines of water; but it is the breaking up of these masses I would particularly wish you to guard against, always bearing in mind it denotes greater talent in those who can "simplify," rather than in those who "cut up" or complicate their productions. For instance, see that your distance is not "broken up" by, say, an open row of trees cutting across it on to the sky line, thus rendering patches of distance as seen between the trees as patches also of the trees themselves (Fig. 5). Get to some other position, in which you can either command the distant prospect without the interruption of the trees, say, above them, or else go closer to them, in order that you may get a view between them, and thus overcome the difficulty (Fig. 6).

Hundreds of otherwise good pictures are quite spoiled through lacking this great quality of "unity" or breadth, whilst those of a very few order excel, in the minds of the vulgar, in its very violation.

Let me give you an example of one of these latter. A little piece of rock here, or a tiny bush there, two stones placed together and another not far off. A winding road which leads to nowhere, cropping up at un-

* Continued from page 376.

expected intervals, serves to offer some foundation for travellers who are seen to keep a most regular and respectful distance from each other. A little to the right is a placid stream of water, with a wonderful lot of rushes of isolated growth and "pot-hook" form. A man in a boat adds life to this portion, whilst a bridge, at no remote distance, affords a vantage ground for one on fishing bent. It would be hard for these poor souls to be far away from any source of refreshment, so a kindly hand

Fig. 5.

erects an inn, and finds a landlord too. You have often seen him. He is most generally to be observed at the door, whilst his wife leans out at the window. Two cows in marching order, single file, one red the other white, go, together with a black horse, to complete the list of all the bodies terrestrial. The prospect beyond is of great variety; heathery

Fig. 6.

moors and glowing fields, rocks of quaint geological formation, and cascades past conception to the ordinary human mind; but at last they are all merged into the distance, and find repose in the "blues."

We have seen, thus far, the most agreeable situation for the "horizon," the position of the point of sight, the tendency of the general lines, the disposition of the masses, and the desirability of maintaining "breadth" to the exclusion of "spottiness" in our pictures. We must now consider the balance of parts, or the relation which one or more masses bear to others in the composition.

Balance of Parts.

A balance of parts does not necessarily mean that equal quantities of the subject should be placed on each side of the picture. We have already noticed this unsatisfactory effect in the view of the roadway as seen from a central position. A great preponderance of your subject may exist on one side, and yet be sufficiently balanced on the other by a group of figures, an object, or a mass of either light or shade. Indeed, it is common, in most landscape compositions, to place a greater mass on one side or the other, allowing it to slope into the distance, the mass being balanced, say, if in a harbour, by "shipping," or, in the case of a roadway, by "animals or figures," the shipping, animals, or figures, *always* holding a secondary position in reference to the amount of space they occupy (Fig. 7).

Fig. 7.

Not only is this arrangement more pleasing in its lines, but it is decidedly more picturesque in the irregularity of its parts. Another very general and agreeable composition is that in which the greatest mass is allowed to take a position a little to either right or left of the centre, sloping towards the sides, the objects which balance it being placed in close proximity (Fig. 8).

Fig. 8.

In the infinite variety of aspect in which nature is presented to us, it is obvious no code of rules could be formulated to adequately suit all circumstances, so that one's own personal judgment must be largely relied upon for selection and arrangement, and, in proportion to the artistic knowledge we possess, so will depend the success or otherwise of our productions.

Strong Lights.

It must be remembered that brilliant light and strength of tone act in a powerful manner on composition. A very small quantity of black and white in violent contrast will require a large amount of middle or half-tone to subdue it and preserve the harmony of the whole.

You will allow me to suggest, when photographing from nature, the necessity of bearing in mind those colours which are likely to give these strong contrasts when reduced to black and white, in order that you may make due allowance for their balance in your composition. I am told it is an excellent plan to use a piece of cobalt blue glass when selecting a subject, as the tones can more readily be estimated by this means rather than on the ground glass.

Chief Point.

Do not forget there should be a *chief point* of interest in every picture which should at once arrest the eye, and in relation to which all other points must be held subordinate. Where this "chief point" should be situated depends very much on the character of the subject chosen, but some points in a landscape are so obviously well suited for this purpose that they should at once be selected and decided upon. In historical or *genre* pictures the chief point of interest is not unfrequently placed in or near the centre, but it is by no means essential it should occupy that position alone.

Having now determined your "chief point," you will arrange the residue of your subject in such a manner as shall keep up the interest of the whole, and present to the eye an agreeable composition. One object should never be placed over another when that other is of equal size or effect, as this, by dividing the interest, would destroy the power of both. For the same reason two objects of the same size and interest should never be placed so as to appear one on either side of a middle object. One must be rendered subservient to the other to overcome this deteriorating effect.

Proportions.

The proportions of pictures may vary with the general forms of the subject selected, but they should never be exactly square. The effect of height is often aided by an upright form, but its height should be evidently more than its width. For landscapes an oblong form is most desirable, varying in length as the prospect demands. W. D. G.

(To be continued.)

ROYAL CORNWALL POLYTECHNIC SOCIETY, FALMOUTH.

The sixtieth annual Exhibition of this Society will open at Falmouth, on Tuesday, August 23, 1892. Medals and prizes are offered in the following departments:—Special Exhibitions of Electrical Appliances, Mechanics, Mineralogy and Chemistry, Fine Arts, Photography, Natural History, "Lander" Competition.

The following are the regulations for intending exhibitors in the photographic section: In all cases it must be stated whether the work is professional or amateur, and the process of production named. All work sent for competition must have been executed within eighteen months of the date of this Exhibition. Carte-de-visite portraits are excluded from exhibition, except when illustrating some special process or novelty. All enlargements for competition must be the work of the exhibitor.

Professional.

Medals are offered for meritorious productions in the following subjects.

Outdoor Photography.—1. Landscape, not less than 20 by 16 inches. 2. Landscape, 12 × 10 inches and under. 3. Genre. 4. Architectural (exterior). 5. Instantaneous, including marine. 6. Animals. 7. Enlargements.

Indoor Photography.—1. Portraits, not less than 20 × 16 inches. 2. Portraits, 15 × 12 inches and under. 3. Home Portraiture. 4. Still life flowers, &c. 5. Interiors, architectural or otherwise. 6. Photo-micrographs. 7. Enlargements.

Amateur.

1. Landscapes. 2. Architectural, exterior or interior. 3. Hand-camera work, not less than twelve examples. 4. Instantaneous, including marine. 5. Still life. 6. Enlargements.

Photographic Apparatus.

With a view to offer facilities to manufacturers to bring their specialities prominently before the public in the West of England, the Society purpose this year to apportion space for photographic apparatus generally, including the lantern and its appliances.

Further information respecting the photographic department may be obtained from Mr. W. Brooks, Laurel Villa, Wray Park, Reigate.

LINCOLN CAMERA CLUB EXHIBITION.

On Wednesday, June 8, the Bishop of Lincoln opened a photographic exhibition at the Schools of Science and Art, Lincoln, which is being held under the auspices of the local Camera Club. The display has been got together by means of special invitations sent out to well-known men, and the exhibits which form the nucleus of the whole have come from the exhibition of English Art Photography recently held in Brussels.

The local press speaks enthusiastically of the pictures shown, most of which are already familiar by reputation to our readers. The idea of bringing examples of the works of all the best known photographers to Lincoln is due to Mr. R. Slingsby, who wrote personally to the Brussels exhibitors, each of whom acceded to the request for work to be forwarded to Lincoln.

At the inaugural proceedings the Bishop of Lincoln was called upon to open the exhibition. The Bishop lightly touched on the history of photography, and gave an interesting and humorous account of his own experiences as an amateur photographer. Proceeding, his Lordship asked the members of the club to see if they could not put into their pictures something of feeling, thought, mind, and soul. It was wonderful what photographs did for them. By their means they could in their own homes look upon the wonderful architecture of Egypt, and upon the scenery of foreign countries. The astronomical and other uses of photography were marvellous. Who could estimate the moral support which a mother's photograph had been to the lad who had gone across the seas to seek his fortune? Many and many a man had in his breast pocket a photograph which had been the star of his life, and had guided him safely over the troubled waters, and through the different temptations which beset him. Let him, if he might, utter one word of caution. He did hope that Society would set its face against and banish indignantly those photographs which a man would be ashamed to look upon if his wife or mother were standing by. He held it to be a disgrace and a wrong upon art for a man to hang upon his walls a photograph the original of which he would be ashamed to be in the company of with his wife or sister.

Our Editorial Table.

The "Fallowfield" Camera.

This is an emanation from the fertile brain of Mr. F. Miall, well known as the inventor of the "Facile" and other cameras. In devising this camera Mr. Miall has introduced a variety of original and ingenious mechanical expedients to secure automatic action. It is arranged for either being used as a hand camera or for being placed upon a stand, and it differs from the "Facile" *inter alia* in this respect, that the subject can be focussed from a distance of three feet to infinity and that the focussing can be done either by a graduated scale or by direct observation on a ground glass the size of the plate. The lens has an iris diaphragm which is opened or closed from the outside, and the shutter is controlled by a brake which enables an exposure of from two seconds to the hundredth of a second to be given, with the option of giving a time exposure when the subject demands it. Another prominent feature is a removable magazine, in virtue of which when the first dozen of plates has been exposed the receptacle containing them may be withdrawn from the camera in full daylight and another magazine inserted in its place.

In these cuts are shown the "Fallowfield" as carried in the hand, the second view given being that of the bottom, which is unseen by the ordinary observer. In this, K is the arrangement for changing the plates, the one selected for exposure being determined by moving the index lever to any special number when plates of different degrees of rapidity are stored; or, of course, they may be exposed in rotation. At the front end the movements of E and H respectively determine the speed of the shutter and the aperture of the iris diaphragm. The other pieces of mechanism are sufficiently obvious not to need special description. Still, we may point out that D, by pressing which the exposure is given, enacts the further useful part of having opened an internal flap which shuts off all light from the plate, the terminal part of the pressure on D liberating the exposing shutter in the lens. By

an automatic arrangement the mere act of withdrawing the magazine of exposed plates closes it up securely against the admission of light, the act of pushing in the succeeding magazine equally and automatically removing its light-tight lid. There are two finders. The camera is neatly covered with crocodile morocco leather. It works with absolute certainty. During the short time it has been in our possession we have exposed and transferred several dozens of plates without experiencing an approximation to a hitch. As will have been inferred from the name it is sold by Mr. Jonathan Fallowfield, 146, Charing Cross-road.

From Messrs. G. & W. Wimpy, 365, Goldhawk-road, W. (the Rembrandt Studio), we have received specimens of their trade work, consisting of charmingly worked-up bromide enlargements, artistically finished in black and white. In one of these the head, a profile, is well relieved by a sketchy floral background, which much conduces to the fine effect. If this young firm continues to issue work of equal merit, many of the profession will avail themselves of their services.

The Strand Magazine for June takes us into the interior of a sculptor's studio, and, aided by numerous illustrations, shows us how a sculptor works, from the framework forming the support of the clay up to the finished model. The portraits of celebrities, at different times of their lives, embrace Sir George Trevelyan, M.P., W. P. Frith, R.A., B. W. Leader, A.R.A., Miss Lily Hanbury, Sir Henry Parkes, and Jacques Blumenthal. Madame Adelina Patti forms the subject of the illustrated interview. The *Magazine* is profusely illustrated.

The 1892 Catalogue of Messrs. E. & T. Underwood, of Granville-street, Birmingham, is rich in particulars and illustrations of the latest and most improved forms of cameras, shutters, tripods, and other apparatus manufactured and introduced by this house. The Catalogue also contains some serviceable hints on the uses of their cameras, lenses, &c., which, being of a high class, enjoy a well-merited popularity among professional and amateur photographers.

PATENTS COMPLETED.

Improved Method of Obtaining Solar Altitudes by the Aid of Instantaneous Photography.

No. 10,101. John Joly, 39, Waterloo-road, Dublin, Ireland.—*May* 14, 1892.

The method consists in photographing instantaneously the sun and horizon so that from measurements made subsequently upon the plate, the angular distance of the sun and the horizon at the moment of taking the photograph can be ascertained. I preferably carry out my invention by affixing to a Hadley's sextant a photographic apparatus, replacing the usual eyepiece or telescope, which, when the moveable limb of the sextant is so set that the sun and horizon are brought into approximate coincidence and the observer, through a suitable sighting glass, points the instrument at the sun or horizon, then, upon releasing a shutter, the photograph taken of the direct and reflected images shows the exact want of coincidence of these, and so affords a correction which, applied to the setting of the sextant, gives the true altitude. To fix the time of observation accurately, I may simultaneously photograph the dial of a timepiece.

Improvements in Apparatus for Changing Sensitised Plates for Photographic Cameras.

No. 11,728. Walter Edmund Kerslake, 47, Garrick-street, and Peter White Johnson, 5, West-road, Elm-park, Ullet-road, Liverpool, Lancashire.—*May* 14, 1892.

This invention has reference to a changing bag and means for attaching the same to the dark slide of a camera so that sensitised plates can be transferred from the bag to the slide, and *vice versâ*, and the object of the invention is to ensure the bag being closed so as to exclude all light from the plate when the latter is in the bag, and also to provide means for attaching the bag to the dark slide, such that the plate can be readily transferred from the one to the other without admitting any light thereto.

We provide a bag sufficiently wide to contain the intended plate, but somewhat longer than the latter; the bag is made of any suitable material which is quite opaque to actinic light; we find waterproof cloth or thin sheet india-rubber suitable for the purpose.

We line the interior of the mouth end of the bag with velvet, plush, or other pile material, the lining extending a little over the edge of the plate when the latter is within the bag, so that there may be no liability of the plate catching the edge of the material as it is being withdrawn.

At a short distance from the mouth of the bag, but between the mouth and the edge of the plate, we attach a strip of metal, or other suitable material, to each of the opposite sides of the bag. These strips are nearly as long as the width of the bag, and placed preferably between the pile material and the outer material of the bag. It will be seen that when a rubber band is stretched round the bag and over the strips, the pile material lining the bag is brought into close contact, and so closes the bag and excludes the light.

In order to more effectually exclude the light, we corrugate the slips longitudinally, that is to say, the corrugations are parallel to the mouth of the bag, and they are so arranged as to interlock; and in order to stiffen the bag, we attach a metallic frame to the bottom and two sides. The section of the frame is preferably U-shaped, the concave side being inwards; this also serves to protect the edges and corners of the bag against wear.

The dark slide, which fits the camera in the usual way, and which has an ordinary sliding door to expose the plate, is provided with a rectangular tube, corrugated transversely, over which the mouth of the bag stretches, and through which the plate is passed into a groove in the slide, the corrugations serving to more effectually exclude the light, and to prevent the bag slipping off.

The mode of using the bag is as follows:—

A sensitised plate is placed in the bag in a dark room, and the bag closed by placing a rubber band over the strips. When it is desired to place the plate in the dark slide, the mouth of the bag is stretched over the corrugated tube, and the rubber band is removed from over the strips and placed round the tube (or two rubber bands may be used); the plate is then transferred from the bag to its position in the dark slide and the exposure made, after which the plate is transferred back to the bag.

The dark slide may, if desired, be fitted with ground glass for focussing, said glass being arranged to move back to admit the plate; the dark slides may also be made single or double, as preferred.

The mouth of the bag may be corrugated so as to form a better joint with the corrugated tube, and metallic springs may be substituted for the rubber bands.

The portion of our invention relating to the corrugating of the bag and tube is also applicable to changing boxes and other devices for changing sensitised plates.

Improvements in Portable Photographic Apparatus adapted to Take Views.

No. 12,374. William Ford Stanley, 13, Railway-approach, London Bridge, S.E.—*May* 21, 1892.

The object of my invention is to construct a camera, with its stand or tripod, for taking large views, in so portable a manner that the whole apparatus may be easily carried by one man, also to make the camera in a special light manner, with arrangements for enclosing or boxing-up the whole of the parts liable to damage, so that when closed the outer parts of the camera form a box or suitable case to contain the camera, focussing screen, and a number of double dark slides. The stand is constructed so that it packs in a small space, with a form of slide specially adapted to this camera that will not jamb or stick in its parts if wetted or exposed to damp. And an arrangement for holding the camera steady when upon the stand.

To carry my invention into effect, I construct my apparatus as follows:—

The camera, a convenient size of which is for carrying plates 15 × 12, but it can be adapted to any size, is formed within a case, just large enough in width

and depth to carry the dark slides, and the thickness through is governed by the number of dark slides to be carried. Three is a convenient number, holding six plates. These, with the focussing screen, are placed against the back of the case, and just in front of them a suitable frame which the dark slides or focussing screen bear against, and the bellows body of the camera is attached. This frames comes about the centre of the case, and is fitted with a spring piece at its upper part to bear against the dark slides and prevent any possibility of light entering. The front portion of the case contains the folded bellows body and wood front for carrying the lens; the bellows is tapered so as to fold more compact, and is of oblong form, so that the lens front may be fitted with a peep-hole or lens for focussing from the front. This peep-hole is fitted with a suitable light-tight shutter. The front of the case is hinged so as to open down and form the baseboard of the camera, it being held in its position by suitable metal ties which clamp by set screws running in slides upon the sides of the case. The inside of this flap is provided with slides, in which the lens front of the bellows body moves, fitted with suitable means for clamping the lens front to focus in any desired position.

The top of the case is hinged at the back part so as to open for changing and operating the dark slides. The dark slides are made as light as possible, and provided preferably with vulcanite shutters. The focussing screen is preferably formed by stretching a sheet of drawing paper on a suitable frame. Space is left at the back of the case behind the dark slides to contain the shutter of a dark slide when it is removed for taking a photograph. Suitable arrangements are made in the bottom and one side of the case for attaching to the stand for either portrait or landscape views, and locks, catches, and other fastenings are provided for keeping the hinged flaps closed to box up the instrument when out of use.

The stand is made of a usual sliding form, with either one, two, or three slides, and as light as possible consistent with strength, but with the following essential difference, that, as hitherto all sliding camera-stands have been made to slide by means of square grooves on each side of one piece and square projections upon the other, so that if the wood gets swollen at all by wet or damp the slides jamb or stick, thus causing a considerable amount of inconvenience to the user, with this improved stand, instead of making square grooves and square pieces to slide in them, I make the grooves and sliding-pieces V shape, and provide a suitable clamping arrangement round the legs, so that by slackening back the clamping screws the sides are perfectly free to run easily, and, when in any desired position, they are clamped with greater rigidity by means of the clamping arrangement. The clamps are preferably made by bands of metal encircling the lower part of each section, provided with a suitable screw arrangement at one side, by which the legs are clamped together. By this arrangement it will be seen that the slightest turn of the clamping screws will cause the slides to fit quite tight, or, by release, be perfectly free, no matter whether the wood is swollen by wet or not.

The steadying arrangement is made as follows. In any suitable position upon the camera, preferably on the large flap that opens down, forming the base, a stud is affixed, and round this stud a cord passes to two suitable spikes, preferably fitted with handles, by which they are pressed into the ground, and the cord is provided with an arrangement for adjustment, preferably similar, but on a small scale, to that used for tent ropes; the cord runs through eyes in the handles of the spikes, so that no other fastening is necessary, and is tightened up by the above described means, thus forming a stay in two ways from the camera to the ground, to prevent the effect of wind upon the camera.

The whole of the camera and fittings is provided with a suitable waterproof canvas case, which is constructed to be carried knapsack fashion upon the back of a person, the said case being also fitted with a suitable handle for carrying by hand if desired.

Various modifications may be made, and any suitable materials used.

PHOTOGRAPHIC SOCIETY OF GREAT BRITAIN.

JUNE 14th.—Ordinary Meeting.—The President (Captain W. de W. Abney, C.B., F.R.S.) in the chair.

Mr. H. A. Lawrance was elected a member, and six other gentlemen were nominated for membership.

It was announced that the Madras, Putney, and Saltburn-by-the-Sea Photographic Societies, and the Cleveland Camera Club had been admitted to affiliation of the Society.

ORTHOCHROMATIC PHOTOGRAPHY.

Dr. J. J. ACWORTH, Ph.D., F.I.C., F.C.S., read a paper on *Orthochromatic Photography*, in which, after saying that he proposed to confine himself to a few scientific facts, and digressions therefrom, he described the uses of the spectroscope in observing and photographing absorption bands of various dyes, dyed emulsions, &c. One class or series of dyes was more particularly used for orthochromatising than any other—the so-called eosine series. For yellow sensitising one dye had hitherto been preferred, as it gave less slowing action in the blue, and that a tetra-iodo, fluoresceine, or erythrosine; for green, uranine, or the soda salt of fluoresceine now commercially used; for orange, red quinoline blue or cyanine is employed. Dr. Vogel's secret "azaline," for red sensitising, was composed of quinoline red, with a smaller proportion of quinoline blue (cyanine).

He had no doubt that, although one or two of the so-called eosine group of dyes were now mostly used in orthochromatic photography, other dyes were equally or even more suitable. Even now they had the rhodamin series of dyes quite outside the cosine group; but he was somewhat doubtful if, after all, dyeing a plate was anything like a perfect method of making it more sensitive to the less refrangible rays of the spectrum. Captain Abney had shown how bromide of silver can be made sensitive to the red and even ultra-red rays, and this without any addition of dye. Certain brands of plates possess far greater yellow sensitiveness than others did, they but work with the idea of making undyed bromide of silver yellow sensitive instead of blue sensitive. A solution of erythrosine added to a gelatino-bromide emulsion instantly made it sensitive to the yellow rays. By adding ammonia the sensitiveness to the yellow rays was no more increased than was its sensitiveness to the other parts of the spectrum. Adding some erythrosine—in fact, a very minute trace—to some more of the same emulsion, and then some silver nitrate, they got a combination between the silver and the dyed emulsion, and this caused the emulsion to become far more sensitive to the yellow rays, and, in fact, far more sensitive to all the other spectral regions of the less refrangible end.

In connexion with orthochromatic photography he mentioned the names of three workers—Dr. Eder, Dr. Vogel of Berlin, and Mr. Clayton, an orthochromatic plate-maker of Paris. The latter two had one thing in common—they were patentees of orthochromatic methods. The Tailfer and Clayton patent, January, 1883, claimed the use of ammonia in conjunction with the dye because "eosine gives no result unless it is introduced with ammonia as a vehicle." This was an assertion absurd and contrary to fact, as mentioned by Mr. Bedford a year ago. It was the combined use of ammonia with eosine that formed the essential feature of the patent. It says to every 100 grammes of emulsion you must add one gramme of dye. This is what he did to a certain extent. This dyed emulsion possesses a greatly reduced sensitiveness to the blue rays, about one-third or a quarter of the original, whilst the yellow sensitiveness is very high, and equally so whether ammonia be present or not. Of course, they were aware that plates are not, nor could be, prepared in such a manner, the enormous quantity of the dye alone greatly interfering with the practical working of the plate. Another point worthy of notice was, that as most of the gelatino-bromide plates were prepared by means of ammonia, this patent, if it could be maintained, would have the consequence, when cosine dyes were present, of preventing the preparation of plates by the usual method of making emulsion, which to his mind seemed extraordinary, to say the least.

Professor Vogel's patent appeared to his mind as the only real patent of any commercial or practical value that has ever been taken out for the manufacture of orthochromatic plates. Its essential feature or claim is the combination of the dye with silver, or formation of eoside of silver. All orthochromatic plates to-day were, he believed, made under this patent. In the case of Vogel's patent we can use, instead of a large amount of dye, merely a few milligrames, these few milligrammes giving an effect infinitely so superior to that obtained with the larger amount of dye that we can no longer compare them. They had heard a good deal of discussion about optical and chemical sensitising. He thought it was becoming recognised that Tailfer's method should be described as optical sensitising, and Vogel's chemical sensitising, the latter giving far superior results to the former. This patent had already lapsed for nearly a year. To prove that orthochromatic plates are made according to Vogel's eoside of silver process, they had only to treat a plate with a solution of potassium bromide, which would to all intents and purposes deorthochromatise it. The practical orthochromatisation of a whole plate may be destroyed by a single milligramme of potassium bromide. Potassium bromide is usually added to emulsions to cause them to keep, so you can understand the reason why orthochromatic plates are supposed to deteriorate so much more quickly than ordinary plates.

The following results of experiments bore on optical and chemical sensitising.

Nos. I., II., and III. were separate emulsions, each containing 30 c.c. of ripened emulsion and ·05 gramme erythrosine.

To I. added nothing; to II. added ·05 gramme $AgNO_3$; to III. added ·5 c.c. AmHO. Tested wet in the spectroscope.

No. I. showed a small band of yellow sensitiveness.

No. II. showed a vastly increased sensitiveness to yellow (eight to ten times greater), and the band of sensitiveness now stretches without a break, though of course, of reduced intensity, through the green right away to the blue violet.

No. III. General sensitiveness to the whole spectrum was increased, but sensitiveness to the less refrangible end did not appear any more increased than does sensitiveness to the more refrangible end

No. IV. To 30 c.c. of emulsion ·010 gramme of erythrosine and $AgNO_3$ sufficient to form erythroside of silver was added. In this case the maximum effect in the yellow was attained, and practically little, if any, loss of blue-violet sensitiveness. From this it was obvious that large quantities of the dye were superfluous and injurious. The maximum effect could be obtained by using far less than even this latter amount, for he found that 1 mgr. or even ·5 mgr. of erythrosine to 30 c.c. of bromide emulsion would, if the dye be perfectly associated with silver, still give a maximum effect in the yellow.

He had also tried the combination of uranine and erythrosine, and with satisfactory results, as the following experiment showed:—

To 30 c.c. of emulsion he added ·030 gramme uranine and ·05 gramme of $Ag\,NO_3$. This gave a splendid band in the green. A small quantity of erythrosine—say 1 mgr.—did not seem to give a good result in the yellow; but

when the amount was increased to 5-10 mgr., yellow sensitiveness was obtained. He further made a uranin-erythrosine emulsion, containing ·030 gramme of uranin and .015 erythrosine, the emulsion containing silver equal to 5 grammes of nitrate and sufficient free silver to combine with the dye. To a portion of such emulsion potassium bromide was added.

The normal uranin-erythrosine dyed emulsion gave a curve of sensitiveness similar to No. I. That to which a small portion of bromide was added, a curve similar to No. II. It will here be seen that yellow-green sensitiveness has been vastly depreciated in comparison with that of blue sensitiveness—in fact, the emulsion was practically deorthochromatised. A plate coated with the normal emulsion, and treated subsequently with potassium bromide, produced a similar degradation of yellow-green sensitiveness.

M. Léon Vidal said in France very few plates were sold made by the Tailfer-Clayton process, which was worked solely by the patentee, these plates being of a quality much inferior to those made by the famous firm of Lumière, of Lyons. The plates of this latter firm, which were so much esteemed in France, were made in a manner quite different from that of Tailfer-Clayton, and were prepared in two series, the one sensitive to the yellow-green rays and the other sensitive to the red. Through the courtesy of Messrs. Lumière, he had received some of these plates for testing. When examined spectroscopically, the yellow sensitive plates show a band of sensitiveness similar to that when erythrosine is used. Those sensitive to red show a band of sensitising action in the red. Both are remarkably fine and clean working plates. M. Jissandier, at Paris, also makes orthochromatic films by another process. The well-known firm of Dr. Monckhoven, of Ghent, also makes orthochromatic plates by a process which he has himself elaborated. M. Vidal says that the so-called patent has hindered any advance of orthochromatic photography in France, until a few high-class firms, possessing both intelligence and enterprise, have neglected the patent, and worked out something better without it.

For scientific purposes he had made plates sensitive, practically, to all the rays of the spectrum. For this purpose he used tincture of jaborandi, and used the tincture in combination with silver nitrate and ammonia in the emulsion. Of course, chlorophyll was the chief colour sensitiser here. The results were, however, somewhat uncertain, and the plates kept badly. With these plates, however, he photographed the solar spectrum, and obtained the photograph of the lines from A in the red right away to H, and beyond the violet on the same plane.

Concluding, he touched upon orthochromatic collodion work in Germany, which he thought disappointing compared with gelatino-bromide work, and spoke of the use of the coloured screen, the necessity for which depended on the relative sensitiveness of the plate to the blue and yellow, on the predominant colours of the subject, and on the quality of the light. At the termination of the paper, he showed examples of natural colour photography by Dr. Vogel produced by using plates sensitised for the different colours, the colours of the collotype print being determined by those of the subject. Dr. Vogel said there was no patent in Germany for orthochromatic photography, which was an imitation of Waterhouse's work, and therefore there was no invention in it.

The PRESIDENT said that, in the discussion, he must ask them to avoid legal questions. He should rule questions as to patent rights out of order. They must confine themselves to the scientific and artistic sides of the subject, as they had quite sufficient to discuss without making themselves a small court of law.

Dr. G. LINDSAY JOHNSON asked for information as to how long orthochromatised plates would keep, compared with non-orthochromatised plates; also, was any special formula better than others?

Mr. J. SPILLER said that although the subject was not new, he felt great interest in it. Dr. Acworth had done wisely and well in bringing it before the members of that Society in a true, scientific spirit. There were one or two details in the paper as to which he was inclined to join issue with Dr. Acworth. First as to optical and chemical sensitisers. Were they really not one and the same thing? Dr. Acworth had mentioned that, by the application of a small quantity of dye, adding at the same time a certain proportion of silver nitrate, the emulsion could be orthochromatised with a much smaller amount of colouring matter. At first sight this was a very important step in the direction of progress; but would Dr. Acworth assert that plates prepared this way had any permanent qualities? Was it possible that plates with free silver nitrate would keep? Then, when erythrosine came into contact with bromide of silver, a chemical change occurred by the interchange of bromine and iodine, which was often lost sight of. The familiar reaction, Ag Cl + KI = Ag I + K Cl showed, substituting erythrosine or fluorescein, that a change occurred. Iodide would be formed in the film, and erythrosine was no longer in the mixture as a colouring matter; the iodine had gone to the silver. They used erythrosine as a simple dye, in order to tint the film, but whether it was used in that form, or first combined with silver, as Vogel would recommend, it came to the same thing in the end. There was a sharp line between optical and chemical sensitisers, because, in the latter, decomposition occurred which would eventually bring about a change.

Mr. W. E. DEBENHAM said that Dr. Acworth had told them that a small quantity of bromide of potassium was sufficient to deorthochromatise a plate, but were the emulsions other than orthochromatic emulsions, not made with erythrosine to start with, not made with the usual excess of bromide? Otherwise, they would be deorthochromatised at once. With regard to Mr. Spiller's equations, did the iodine go over to form iodide of silver associated with some complex body or a simple potassium body? His own experiments fully confirmed Dr. Acworth's statement that ammonia was not in the slightest degree necessary for making orthochromatic emulsion plates, or for sensitising plates already prepared. He had sensitised ordinary commercial plates with erythrosine, and found that the resulting plates were as nearly as possible identical with commercial plates. Several had repeated the same experiment and the same statement. It was surprising to find the assertion depended upon in any way that erythrosine without ammonia is useless in an emulsion, or does not produce its full effect. As to the effect in collodion, he found it much the same as with gelatine plates. The plates which showed the best effects without a screen were those prepared with collodion. Erythrosine plates prepared in the ordinary way, without a screen show very slight effect. He did not know whether Dr. Acworth had gone into the amount of slowing which a screen produced on an erythrosine plate. He (Mr. Debenham) had found that a yellow screen, which slowed an ordinary plate four times, only slowed an erythrosine plate about twice.

Mr. J. R. GOTZ said that he had had Dr. Vogel's azaline in his hands for the last six years at least. With respect to another matter that had been mentioned, as to Dr. Vogel being one of the first to make experiments with orthochromatising bromide of silver plates, he thought that their President made the same experiment as Dr. Vogel at the same time.

Dr. J. J. ACWORTH, in the course of his reply, said that, so far as his experience went, orthochromatic plates did not keep so well as ordinary plates, for the reason that soluble bromide was added to an ordinary emulsion to make the plates keep. With regard to a large amount of dye as against an extremely minute amount, Dr. Vogel said that he liked to use the large quantity, but he (Dr. Acworth) preferred the small quantity. It was the large amount of dye mentioned in the Tailfer patent he was speaking of, which was absurd for all practical purposes. As to Mr. Spiller's remarks regarding the free nitrate, there should not be excess of silver. He doubted whether iodine was dissociated from the body itself, as suggested by Mr. Spiller, but he (Dr. Acworth) could not say. Orthochromatic plates could not be made with excess of bromide. The limits of adding erythrosine were very wide; a large amount of dye degraded blue sensitiveness, but did not affect the yellow to any appreciable degree. Employed as an optical sensitiser, a large amount of dye must be added to get any result at all. The finer results given by collodion were due to the collodion having free silver.

Dr. LINDSAY JOHNSON said there were two points as to the qualities of orthochromatic plates to which he would like to refer. Many people had the idea that the plates in the market lost orthochromatic qualities, but remained the same as ordinary plates. He would like to know whether a good orthochromatic plate in keeping would retain its photographic quality, without its orthochromatic quality, or whether one goes or both. He had got plates from a well-known firm in London, and kept them for a year and a half, and found they were quite as good as when they went out.

Dr. ACWORTH, in reply, said that he did not think it hardly possible that the orthochromatic effect could be lost, or not unless the plate went wrong entirely. He had found some plates kept very well, and others badly. It hinged upon one or two details of the *modus operandi*.

The PRESIDENT, in closing the discussion and moving a vote of thanks to Dr. Acworth, which was carried, said that, regarding the large quantity of emulsion orthochromatised by a minute quantity of colouring matter, his own practice was to pour it on the plate as collodion, and wash out as much as ever he could, so that he could not distinguish the plate from an ordinary plate. He had described the method at the Camera Club some time ago. Using cyanine after erythrosine, he worked the same way, washing between each. Mr. Debenham made a remark which recalled an experiment of his (the President's) made many years ago. When Dr. Vogel first gave them the benefit of his experiments, he said that he (the President) could not get an orthochromatic plate with an excess of bromide, but he got it, and the Doctor said he didn't. An emulsion with excess of bromide could be orthochromatised. The most perfect dye was the combination between erythrosine and cyanine. Used separately they could get the whole of the spectrum from beginning to end. Eikonogen development gave good results. As to optical and chemical sensitisers, Dr. Acworth had taken quite the reverse view of Dr. Vogel, who conveyed quite a different meaning. Dr. Vogel said that an optical sensitiser was where the dye itself was optically sensitive. There was a crucial experiment which told whether the interchange Mr. Spiller referred to took place. Pure erythrosine was fluorescent, and if the combination occurred, they got eosine, which was not fluorescent. He presumed that double decomposition took place, because that interchange was obtained. M. Vidal had thought orthochromatic plates the most suitable for stellar photography, and he (the President) agreed with him, but their telescopes were not corrected. They should use a reflector instead of a telescope, and they would get better results.

PHOTO-TECHNICAL EDUCATION "AT HOME AND ABROAD."

Mr. E. H. FARMER read a paper on this subject, beginning by saying that in November last Mr. Warnerke, a member of the Council of the Society, read a paper entitled *Photo-Technical Education on the Continent of Europe*, and therein said:—"First of all, he would *give the reason why the Council* had asked him to read such a paper: *We had no establishment in this country which gave instruction in photo-technical education.*"—*Vide* THE BRITISH JOURNAL OF PHOTOGRAPHY, November 12, 1891. Mr. Farmer said this statement and its equivalent, by word, and a great deal more by inference, had gone forth to the public press by the authority of the Council; an authority which, as the representative of the Photographic Society of Great Britain, is, in name at least, the highest authority on photographic matters in England. He wished to say that, however much it might concern him personally as a public teacher of photo-technology, he wished to sink his own identity and to appear before them as the official mouthpiece of the Polytechnic. The force of this derogatory statement could only be fully appreciated by taking into consideration the circumstances which led to its being made. The Council decided that a photographic institute, one of whose chief functions would be photo-technical education, should be promoted in London under the management of this Society. As a worker in the cause of British photography, he was glad to welcome the prospect of the new photographic institute. But while the Council commissioned their agent to tour the Continent of Europe and survey the photographic schools, large and small, which are there to be found in conjunction with polytechnics and technical schools, they not only neglected to recognise the schools already existing in England in connexion with similar establishments, but, on the contrary, allowed their representative to state, and the public to infer, that there were none. It was not his intention to discuss the scheme of the proposed Institute, although, at all times, he would feel the utmost desire to do all he could to promote so excellent an object; but it was his duty to lay before them a brief *résumé* of the facts he had been able to compile in comparing the Continental schools with the work of the Polytechnic. In making this comparison, he did not wish to disparage in any way those institutions on the Continent. The salient points of comparison in the

various schools were these :—I. The buildings, appliances, and endowment funds. II. The fees paid by students. III. The code of instruction. IV. The number of students. V. The results of the teaching.

Mr. Farmer then gave a history and description of the Polytechnic School of Photography, comparing it with the Continental schools, and concluded: "I have said enough, I hope, to show that *we have* establishments in England where photographic technical instruction can be obtained, and I believe that any unbiassed inquiry into both will prove that whether 'the number of the students,' the degree of advancement to which the instruction is carried, 'or the results of the instruction,' be taken in comparison, the work of our school at the Polytechnic will compare most favourably with that done in any school on the Continent. In view of the facts I have laid before you, I trust your Council will see the advisability of publicly removing, in no half-hearted or niggardly manner, the stigma they so unwarrantably cast upon English photographic education, and on our school in particular; and as I understand that this is the last meeting of the Society this session, I would point out that anything they intend doing must be done at once."

Mr. W. S. BIRD regretted Mr. Warnerke's statement did not cover the whole of the ground. The Polytechnic School could have brought it to the notice of the Council. The statement did not appear in their own journal. He was sure there was no intention to do any harm.

Mr. W. BEDFORD said there was one thing to be borne in mind as to the unfortunate remark which Mr. Warnerke was reported to have made, and that was, Mr. Warnerke had no mission to go abroad; he was simply asked to read a paper. The sentence did not appear in their own journal, so that, perhaps, on second thoughts, he saw the remark was not justified.

Mr. DEBENHAM thought Mr. Farmer had misconceived the position. Mr. Warnerke did not represent the Council; things might be represented in the paper over which they had no control.

Mr. T. SEBASTIAN DAVIS believed that on the occasion in question Mr. Warnerke's point was that there was no society or institution supported by Government in which the subject of photography was taught, and he thought that was the general impression. He was sure they were all pleased to hear Mr. Farmer's excellent description of the Polytechnic Institution, which was conducted without Government aid.

Mr. CLIFT believed Mr. Warnerke had the subject of photo-mechanical printing in his mind. There was no school whatever in this country, and the proper workers could not be had in England.

Mr. T. R. DALLMEYER thought most of them understood Mr. Warnerke to have that meaning. M. Léon Vidal had recently assured him (Mr. Dallmeyer) that we were behind France and Germany in respect of photo-mechanical work.

Mr. ANDREW PRINGLE agreed with the views of the preceding speakers, and said he thought the business of the Polytechnic Institution was with Mr. Warnerke personally rather than with the Society. There was no such statement as Mr. Farmer complained of in their official transactions. It had only been reported in THE BRITISH JOURNAL OF PHOTOGRAPHY. Mr. Farmer had misunderstood Mr. Warnerke, and should have applied to Mr. Warnerke for assistance.

After some further discussion, Mr. FARMER replied.

The PRESIDENT, in closing the discussion, said the Society was sorry if, by any means, it had given countenance to the idea that it had slighted the Polytechnic. Nobody knew more than he did regarding the amount of instruction given there, and he had reason to believe that every word Mr. Farmer said was absolutely correct. He had been Examiner of the City and Guilds Institute for some time, and he was perfectly ignorant where the papers came from, but he found that the Polytechnic was generally to the fore. Photo-mechanical process work was a fixed idea in Mr. Warnerke's brain, and he (the President) was perfectly certain that when Mr. Warnerke was making his introductory remarks, he was thinking of instruction in photo-mechanical printing. He (the President) might have taken objection to the remarks, as there was a photo-mechanical printing establishment at Chatham, of which he (the President) was the founder; but it never struck him as having any bearing on the case. He asked them to show, by their applause, that there was not the slightest intention in any way, on Mr. Warnerke's part, in his introductory remarks, to slight the Polytechnic, and that they regretted it for him and for themselves.

Mr. Farmer having been duly applauded, the meeting terminated.

LONDON AND PROVINCIAL PHOTOGRAPHIC ASSOCIATION.

JUNE 9,—Mr. T. E. Freshwater, F.R.M.S., in the chair.

Mr. A. E. Smith, of 90, Queen-street, Cheapside, was elected a member.

PROGRESS OF THE AFFILIATION SCHEME.

The HON. SECRETARY read a communication from the Photographic Society of Great Britain, stating that proofs of the papers read before the Society would be available for the affiliated societies, before whom, also, Mr. W. E. Debenham was willing to lecture. Members of affiliated societies would at the forthcoming exhibition be entitled to a remission of half the charges for wall space and on the tickets of admission. The following societies had placed their dark rooms at the disposal of members of affiliated societies :—Southsea, Oxford, Hull, Leeds, Liverpool, Darlington, Dorset, North Kent, and the Photographic Society of Great Britain.

EGGS AND SENSITIVENESS.

Mr. W. H. HARRISON quoted a statement of Hunt, that in albumenising paper more sensitive results were got with the albumen from ducks' eggs than from hens', and still more from that of the eggs of geese. The albumen of the eggs of birds of prey was said to increase sensitiveness. Was there any truth in the statement?

Mr. W. E. DEBENHAM said they were so accustomed to hear these statements as to greater sensitiveness, that he thought they might disregard the whole lot. He thought there was little difference in the sensitiveness of any albumenised or gelatine papers.

COLOURED FOG.

Mr. J. E. Smith exhibited a negative developed with hydroquinone followed by pyro-ammonia, in which green, red, and yellow fog were visible.

Mr. A. COWAN said the coloured fog was produced by the combination of hydroquinone with ammonia.

Mr. W. E. DEBENHAM observed that the complementary colours of the fog were visible by transmitted light.

THE YELLOW SCREEN.

Mr. P. Everett exhibited two negatives of the same subject, one exposed with, and the other without a screen, on Ilford medium plates. The exposure with the screen was increased three times. He had tested the screen with albumenised paper, printing to the same tint with and without the yellow screen. The screened negative was in all respects superior.

Mr. DEBENHAM had found that with a pale yellow glass and an ordinary plate he had to give four times; but with an erythrosine plate only twice the exposure. Deep yellow increased the exposure with an ordinary plate twenty, and with an erythrosine plate five times. He had used Edwards', Ilford, and plates of his own preparation. He thought Mr. Everett wrong in his ratios.

Mr. J. S. TEAPE asked if Mr. Everett had been guided in the development by the screened negative, as it seemed to him that the unscreened picture was not developed enough?

Mr. EVERETT replied that development of both pictures was simultaneous, and pointed out that halation was about equal in each case.

The date of the annual general meeting was altered from June 23rd to the 30th.

North London Photographic Society.—June 7, Mr. J. Traill Taylor (President) in the chair.—The members of this Society (and a goodly number of visitors) met on the above evening to hear a discourse by Mr. Redmond Barrett on *Retouching*. Dealing with the ethics of the art, both from an artistic and a commercial point of view, Mr. Barrett pointed out the purpose of retouching, and described very clearly what should be done and what left undone, interspersing his remarks by several amusing anecdotes of personal experiences, and illustrating them by a considerable number of specimens of different classes of work. Mr. Barrett, as was to be expected, dealt with his subject in a thoroughly practical manner throughout, and was highly successful in establishing his possession of a perfect command of all the niceties of his art, as well as in conveying a mass of valuable, instructive hints thereon to his audience. In conclusion, he promised to give the Society another evening later in the season, for the purpose of actual demonstration upon a number of negatives to be provided for the purpose. A conversation followed, and a cordial vote of thanks to Mr. Barrett concluded the meeting. Next meeting, June 21, Mr. J. Traill Taylor on *Photographic Lenses*. Ancient and modern visitors are cordially invited.

North Middlesex Photographic Society.—June 13, Mr. Stanley Barnard in the chair. Two new members were elected, and one nominated for election. Mr. F. E. JONES gave a demonstration on the Platinotype Company's new cold-bath process. He developed prints from hard and soft negatives, and having purposely obtained air bubbles on the surface of a print, showed that they disappeared before completion of development. The points he emphasised were :—That the new process is suitable for use with softer negatives than the hot-bath process, and if a negative gave hard prints, it would be advantageous to over-print and develop on a weak bath. No thermometer or special dish is necessary. In printing it would usually be found desirable to print until detail is visible in all but the highest lights. Paper which had been properly stored for some time would give more half-tone than newly coated paper. The developer is made by dissolving half a pound of developing salts in forty-eight ounces of water. About fifteen seconds' floating is necessary, or longer if there are heavy blacks in the print, or the shadows may be rusty and granular. The used developer should not be kept in a strong light. Mr. Jones answered a number of questions, and stated that an under-exposed print might, in some cases, be saved by slightly heating the developer. A vote of thanks was accorded to the lecturer. Messrs. HOUGHTON & SONS exhibited their hand camera, explaining the action of all the parts. The remainder of the evening was devoted to technical matters arising from questions found in the box. The usual competitions of views taken at recent field-days were held, that for Sewardstone showing the largest number of entries. The vote of merit was won by Mr. H. Smith. The next meeting will be held on June 27, when Mr. F. Tennant will take the chair, and celluloid films will be the subject of discussion. Visitors will be welcome.

Holborn Camera Club.—June 10, Mr. A. Horsley Hinton (President) in the chair.—Mr. E. CLIFTON gave a lecture on *Developing in Practice*, dealing only with development by pyro. He dealt first with the dark room. The most important thing was the light, and daylight should be dispensed with, having oil or gas as the source of light. The next most important point was cleanliness. Many of the mysterious marks and streaks on the plates were due to a dirty and sloppy bench. With regard to developing, Mr. CLIFTON said the preliminary soaking of the plate in water before developing was no great advantage, and gave rise to air bubbles. The best developer for amateurs who had to develop plates exposed on various subjects was pyro-ammonia, using the various ingredients in ten per cent. solutions. For portrait work the soda developer was the best. He had found that the general fault with amateurs was under-development. The plate was not sufficiently developed until the image seemed to be disappearing from the plate, and, on turning it over, the high lights were showing through the bromide. It was better to carry the development too far and then to reduce than to under-develop and intensify. The influence of the temperature on the developer was very great on the density and brilliance of the negative. In the summer the alkali should be reduced. A very good cure for green fog was to immerse the plate in a weak solution of bichloride of mercury for a very short time. This solution would also get rid of metallic lustre, sometimes seen round the edges of stale plates.

Hackney Photographic Society.—June 9, Mr. W. P. Dando in the chair.—Samples of the Barnet plate were distributed. The HON. SECRETARY reminded members that after this month meetings would be held every Tuesday at 206, Mare-street. Mr. DEAN asked how it was he had been troubled with silvering on Ilford isochromatic plates? Mr. BECKETT said it was probably due to having forced the plate, or the fumes of gas having come to them. He advised the use of a wash leather and methylated spirit, which would remove silvering. The CHAIRMAN said he had taken a view in Epping Forest last Wednesday as late as 6 p.m., under trees, with *f*-44, and gave a twenty-seconds exposure, and had to develop it very carefully. The subject was a very dark one. Mr. Beckett showed a picture taken in the Forest, in which he had given over twenty exposures, making over one-minute exposure, the trees being moving at the time. Mr. Goaling showed a snap-shot exposure of tennis players. Mr. SODEAN handed round some microscopical work done on the Imperial plates, which, he said, he was pleased with. Mr. HENSLER asked which was the best exposure for clouds—fast or slow? It was said that a slow exposure later in the day would do, but in the middle a very rapid exposure was essential. Mr. SODEAN then gave a very good account of lenses, *Single* v. *Rapid Rectilinear*, using diagrams. The CHAIRMAN liked single lenses when they were good, but he said they were hard to get. Good makers made a speciality of them. He had used them on architectural subjects successfully, and handed round several prints he had taken in France with single lenses of nine, twelve, and fifteen-inches foci, at an aperture of *f*-8 or *f*-11. The subject then turned to a discussion on *Halation*. Films were considered more rapid than plates, and prevented, in a marked degree, halation. Mr. BECKETT had tried several backings, but preferred that given by Mr. Teape, which was:—Caramel, one ounce (allow a little extra, say, one-third, for waste); burnt sienna, one ounce; methylated spirit, one ounce; water, one ounce. Boil until sugar has lost its taste, which would be about 1½ hour. Mr. Hensler had used several backings, had used among them Bates' black, which was very dirty. The CHAIRMAN said he had reduced halation by using methylated spirit with its equal amount of water. It was a tedious operation, but an interesting book read to him whilst doing it tended to reduce the ennui.

South London Photographic Society.—June 8, the President, Mr. F. W. Edwards in the chair.—A paper was read by Mr. A. Horsley Hinton on *Our Aim in Landscape Work: Some Suggestions, Practical and Otherwise*. The lecturer dealt with many matters relating to the application of art to photography, so that any of the members present might turn his suggestions to account on the next field excursion. To start some thinking and to awaken fresh ideas, and to produce artistic pictures was his wish. If a picture was to express the repose of evening, the sentiment of repose is strongly awakened by the scene selected; inversely, if the scene which arrests attention and moves one to seek its reproduction suggests, when quietly studied, "repose," then the finished picture should also suggest the same feeling. If photography cannot do this, its art claims are utterly vain, and art by photography is impossible. After the selection of the subject comes the treatment. Everything in the picture must be subordinate to the sentiments if there be such an object as a church tower, a bridge, a cottage, clearly defined or strongly indicated, so that the spectator, on looking at the picture, says at once, "Oh, that's So-and-So church," or "Isn't that near such-and-such a place?" It is clear that the component parts of the scene are not subordinate to the sentiment. The remark the picture should suggest is, "That's very restful—so suggestive of evening." Sentiment will never be uppermost when the subject itself is obtrusive, by the very broad or even indistinct representation of the objects we may avoid overpowering any sentiment which may be suggested; by the suppression of the material, we render possible the expression of the ideal; by the subordination of everything that shall of itself excite interest, we give the spectator an opportunity of discovering and recognising the feeling, the idea which in the first instance impelled us to make the picture.

Brighton and Sussex Natural History and Philosophical Society (Photographic Section).—June 10.—The subject for discussion was *Hand Cameras*. Mr. BALDWIN, of the Eastman Company, exhibited and explained the new "Kodaks," which were much admired. Mr. A. E. Stuart showed the "Vanneck," Mr. C. Job showed "Eclipse," Mr. E. J. Bedford "Chadwick." Messrs. Hardcastle and Willi[illegible]n lent various other instruments of this class. Two members also brought cameras of their own designs, and promised to report later on. A special meeting was held the same evening to elect a Chairman, Mr. Caush having been chosen as the President of the Society, and one member to the Committee. Mr. J. P. Slingsby-Roberts was selected as Chairman, and Mr. A. H. Webling as Committeeman. The meeting was largely attended.

Lewes Photographic Society.—June 7, the President (Mr. J. G. Braden) in the chair.—Mr. J. Whittall was elected a member of the Society. Mr. E. J. BEDFORD read a paper on *Perspective as Applied to Photography: the Use and Abuse of Wide-angle Lenses*. He explained, by means of diagrams on the blackboard, the points connected with linear perspective, and which were necessary to know in order to fully understand the action of a wide-angle lens. At the conclusion of the paper a discussion took place, and a cordial vote of thanks was accorded to Mr. Bedford for his paper. The PRESIDENT announced that, as he would shortly be leaving the town, he would be obliged to resign his seat—a proceeding which he much regretted, as he had held it since the com[illegible]ment of the Society in 1888. He congratulated the members on the [illegible] state of the Society, and said he should still continue a member and watch with interest its proceedings. A vote of thanks was passed to the President for the able way in which he has presided over the Society, and which in a great measure accounted for its successful career so far. An excursion takes place on Saturday to Herstmonceux Castle. The Eastbourne Society will join. The train leaves Lewes at ten minutes past twelve.

Edinburgh Photographic Society.—June 8.—The concluding meeting of this Society for the season was delayed for a week, in order that it might be held in the new rooms, 38, North Castle-street, which, although not quite completed in all details, were sufficiently so for this meeting, and will be thoroughly ready before the coming Convention in Edinburgh. The new home of the Society is very conveniently situated, and, when finished, will afford much more comfort than hired rooms for the general purposes of the body although not sufficient for the popular meetings, which require a hall commodious enough to hold at least 800 people. They comprise a large hall, with committee-room on the first floor, and on the next are reading and smoking-room, a large dark room, with all appliances, with private lockers for individual members, and further accommodations for a caretaker are within the building. The chair was occupied by the President, Mr. Blanc, Architect, A.R.S.A., under whose gratuitous and anxious care the necessary alterations have been carried out.

In opening this, the first meeting in the new rooms, he called the attention of the members to the fact that the Society was now in its thirty-first year, and that the modest terms in which the intimation of the opening of the new premises had been stated by the Secretary doubtless arose from the knowledge he had that their new premises would be no more than occupiable at the time, and consequently not in a fit state for members and friends. Fortunate it is, therefore, that a formal opening, with its accompanying address from the chair, are not expected this evening, because, under the present unfinished conditions of our new accommodation, it might be difficult to stir enthusiasm or gather inspiration. With your permission, he said, I am constrained, in a word, to extend to you the Council's congratulations upon the accomplishment so far of the long-cherished wish of the Society, and to express the desire that, with the increased facilities offered by the acquisition of these apartments, the Society will proportionately increase its own usefulness, and add still more to the laudable record it can boast of, as having contributed during the past thirty years some of the foremost thinkers and workers in the art-science of photography. Thirty years is a long vista to look through, and it is a comparatively long life for a Society to boast of. It is doubtful if there are many present or even many on the Society's roll, who are the original men who, in 1861, formed this now popular Society. If there are, then let us extend to them a cordial word of thanks and congratulations—thanks for the fortunate thought that conceived the formation of such a Society, and congratulations on their being able now to witness the happy result of their acts. That movement, from a small beginning, has now developed an Association realising an aggregate as high as that of any similar society in the city, if not the kingdom. Its members have from the commencement steadily increased, notwithstanding the fluctuations incidental to the composition of such societies, and, though its progress in the particular direction of its object has been at varied rates, yet happier are we that the progress has been steady rather than as a series of spasmodic efforts that leave only uncertainty in their train:—

"Science moves but slowly,
Slowly creeping on from point to point."

That alone constitutes true progress. A statistical American once asked one of our recent civic rulers, "What was, or is, Edinburgh's industry?" "Her schools" was the reply—a statement that could have been made with verity 200 years ago, and it is still applicable. Our city has, in short, always taken a foremost place among cities as a nursery of law, medicine, and literature, and to these may be added its societies devoted to the advancement of the arts and sciences. It was natural, therefore, that when the early whispers of the new art-science, which was being diligently studied and experimented with on the Continent by the elder Niepce, assisted by Daguerre, fell upon the intellects of this city, there should be aroused a spirit of earnest curiosity, combined with the desire to penetrate the mine, however deep and dark, and however difficult to excavate. What these two leaders devoutly struggled for was, as we all know, left to Mr. Fox Talbot to accomplish, and by him was the photography we have, with its indispensable repeating negative, made the commercial possibility it now is. A few congenial spirits were known at about the same date, and for ten or fifteen years afterwards, such as Howie, the miniature painter, Popowitz, Orange, Georgiades, mainly foreigners, to work the Daguerreotype process; but the revolution caused by Fox Talbot enlisted at once quite an array of workers who entered the field in our city. Studying as they now practised the fascinating art-science, experiments were made in the effects of light on many different substances, and the outcome was the discovery by Mungo Ponton (1839) of the action of the chromic salts on all bodies of a colloid nature, such as starch, albumen, gelatine, &c., and thus from our own city emanated the carbon process, which, now allied to many others more mechanical, has given birth to so many and wide-spreading industries. Further, from the pages of the Transactions of the Royal Scottish Society of Arts of the same year (1839), we learn that another Edinburgh citizen, C. J. Burnet, first discovered and made freely known what only came into practice many years later, namely, that, to secure the development of the pictures by this process properly, we must expose on one side of the film, and develop on that which had not been exposed to light. It was natural that so interesting a novelty as photography showed itself to be should animate its followers in a like direction, and, as a consequence, the Photographic Society of Scotland was formed, under the highest auspices. Its membership increased rapidly, so fascinating did the new art-study become; but this Society's aims proving too ambitious, and the business of its meetings pertaining rather to dilettantism, it lost popular favour, and gradually passed away. Phœnix-like, however, there arose, not precisely from its ashes, but from its slowly advancing death, a few of the earnest workers who sought to perfect themselves in this special line of knowledge, and naturally so, by friendly meetings at which all new discoveries were brought forward and ideas interchanged. These informal gatherings took ultimate shape, and, after a successful effort at fixing them as weekly meetings, it was finally resolved to constitute a new society, which has continued to bear and to carry on, we submit, successfully and creditably, its work as the Edinburgh Photographic Society. The meeting at which the resolution was carried into effect was held in Buchannan's Temperance Hotel, High-street, and nothing, it seems to me, can be more interesting than to, at this long-after period, recall the names of those present. First we have Mr. J. Traill Taylor, the first Secretary of the Society, and now the well-known editor of THE BRITISH JOURNAL OF PHOTOGRAPHY; Mr. Geo. H. Slight, then engineer and now under the Honourable the Trinity Board; Mr. Andrew Mure, advocate, now Supreme Judge of the recently afflicted Isle of Mauritius; Mr. Archibald Burns, of Messrs. Oliver & Boyd, and well known before his death as a photographer whose negatives of the picturesque bits of old Edinburgh have scarcely been excelled; then we find Mr. Galloway, a writer now deceased; later, James Ramage, the art-manager of the Messrs. Nelson & Sons printing works, and Mr. W. H. Davies, who has held almost every office but my present one in the Society, and to whom, as he has never lost interest in any matters bearing on photography, I am indebted for these very interesting facts. The first members elected after the constitution of the Society, and on the same evening, were Mr. J. Valentine, sen., of Dundee, and Mr. Buchanan, the hotel proprietor, both of whom remained members till their respective deaths. From this it will be seen that the Society was at first chiefly composed of amateurs; but, as photography increased its hold on public patronage, the number of professional members increased rapidly, and so they became blended into the general body of the Society. A glance at the early minutes of the Society is not only interesting, but instructive; as many energetic minds were drawn by sympathy to the various departments of photographic work, the meetings invariably produced something of novelty in mechanical contrivances, or in chemical discoveries, in knowledge of optical science and appliances, and the rapid evolution of new ideas thus produced set the Society afloat on very propitious and popular lines. The Society was honoured by its first President in the person of Mr. J. D. Marwick, then Town Clerk in this city, now Sir J. D. Marwick, City Clerk of Glasgow. He held office for seven years, retiring to create a vacancy that, as he said wisely, fresh life might be infused. He was succeeded by Sheriff Hallard, known in the Society as an ardent and enthusiastic worker in photography, and, beyond that, as a

genial citizen and a fair and impartial administrator of justice. For a long period afterwards professional photographers filled the chair, among whom it may suffice to mention the names of Tunny, Moffat, Ross, and Nelson, and more recently we have had such high professional men as Dr. Sidey, M.D., F.R.S., Mr. Norman Macbeth, R.S.A., Mr. James Lessels, architect, to each and all of whom the Society is more or less indebted. From the beginning, the Society frankly recognised that so interesting a study as photography could not be limited, and so an invitation to ladies to participate in membership was initiated, a call which, however, has been responded to hitherto in a very limited degree. There is no reason why this should not be improved in the near future. With such an interesting record, are we not, then, stimulated to new exertions and to still greater achievements? We have a large and, I venture to think, a vigorous membership, and, with the machinery with which we are about to be equipped, the possibilities of further strides are in our favour. If anything should tend to the consolidation of a Society and be a powerful factor in its development, I can conceive of nothing more potent than the common interest arising from a joint proprietorship. Here we have that interest; for a comparatively nominal subscription we possess a well-ordered suite of apartments, comprising meeting-hall, committee-rooms, smoke and reading-rooms, with facilities for seeing and studying the journals and literature of photography, and the inevitable dark room, with ample store accommodation, and all under conditions which shall render them attractive; and we wait with much interest the result. It would be premature to suggest, and I would therefore postpone to a future meeting the consideration of many projects which occur as to the means by we can make this advance a genuine movement for good, both to the individual members and to the Society as a whole. The age is distinguished on all sides for the acquisition of knowledge; I trust, therefore, this Society will not be found behind in its willingness to give from its stores such knowledge as it possesses, and so increase the attraction to all interested in photography. The formation of sectional classes for instruction, the encouragement of afternoon rambles, a lecture syllabus, annual exhibitions of work, and the formation of a Society album, in which all prints shall be permanent ones, are a few of the many projects that occur as being worthy of being kept in view, and thus extend our influence for good. Among the many causes for congratulation, the acquisition of these rooms at this time is singularly appropriate and satisfactory, as you are aware arrangements are now completed for the reception of the Photographic Convention, whose visit to the city takes place during the week from the 11th to the 16th of next month (July), and your Council feel assured the Convention will gladly recognise the life and energy exemplified by the Society in taking this important step. It is to be hoped, however, that members will not be satisfied to allow the Society to rest its reputation alone upon the exhibition of the new rooms, but will establish the Society's efforts, and verify its existence by a personal presence at the chief gatherings of the Convention. Thus only can the Convention be assured of the reality of our faith and the earnestness of our aims and aspirations. Let us support them loyally as far as is in our power, and help them to carry away happy memories of pleasant associations from our own romantic town. One word more, and I finish. What has been said of our duty to the Convention has greater force applied to our own Society, and I take the liberty to say it, that towards the accomplishments of the Society's aims united action is indispensable, all pointing to the one end, namely, that of justifying the continued existence of the Society by increasing its influence and usefulness, by encouraging a true regard for every one joining its ranks, by courteous consideration of what may seem to be the least important contribution to its business; and, while remembering that all things should be done decently and in order, let us not, by over-zealous desire to abide by that rule, lose sight of the real object of our meetings, our mutual improvement in the art-science of photography.

Correspondence.

☞ *Correspondents should never write on both sides of the paper.*

THE ECLIPSE CAMERA.

To the EDITOR.

SIR,—In the last number of THE BRITISH JOURNAL OF PHOTOGRAPHY there is given the specification of a patent which has been taken out by Mr. Fox Shew for improvements in hand cameras of the character of the ingenious "Eclipse" Camera, devised by George Lowden, and made by Messrs. Shew. The first part refers to a mode by which the camera can be fitted for lenses of different focal length. It is simple, and I have no doubt efficacious, and, though I have not myself had occasion to use lenses of different powers with my camera, it will undoubtedly make this form of camera more generally useful.

The second part has reference to a mode by which "the back of the camera can be adjustably held within certain limits at any angle with the front part thereof," this being accomplished by making the back of the camera of two frames instead of one, to one of which the wings or sides are attached, and to the other the rear end of the bellows body, the one being worked in the other by rack and pinion, and fixed where required by binding screws. This plan I had applied to my camera in March last, principally, no doubt, as a means of focussing (the want of which, except by sliding the lens in a tube, which was unsatisfactory, being a serious defect in the "Eclipse" form of camera), but also to give a limited power of "swing back" to the camera. The main "swing-back" power, however, in my camera, is got by a very simple arrangement of the head of the camera, by which raising the lens is combined with what is equivalent to a swinging of the back. I am thus entitled to claim priority over Mr. Shew in regard to this second part of his specification. I do not, however, desire to interfere with his patent in any way. The improvement was so simple and so obvious (merely an adaptation, in fact, of the old-fashioned double-bodied camera), that it never occurred to me to be worth patenting. It seems now, however, as if any new screw or slot introduced into a camera was worth patenting. I often wonder what my income would have been now if I had patented the "Kinnear Camera," which I invented in 1857, and described in the *Photographic Journal*. As then brought out, with the addition of one or two improvements I made on it next year, and described in the *Journal* of 1859, it is, in all essentials, the camera which is now in universal use, and is made by hundreds of thousands.—I am, yours, &c., C. G. H. KINNEAR.

12, *Grosvenor-crescent, Edinburgh.*

SPEED OF PLATES.

To the EDITOR.

SIR,—Your issue of May 20 contains a letter under this heading from Mr. Alfred Watkins, to which I think some reply should be forthcoming.

I have had considerable experience with the exposure meter, and consider it a valuable photographic instrument. Why? Because its indications give me good pictures. I have also had some experience with the actinograph, and also find this an excellent help, for precisely the same reason.

Moreover, if Mr. Watkins will obtain a dozen plates whose actinograph speed is known, and determine the plate number for the exposure meter, he will be in possession of a ratio which will serve to convert the actinograph speed into plate number for any other plates whose actinograph speed is known.

Let me grant, with Mr. Watkins, that the light of a standard candle is subject to variation; so is the daylight to which the sensitive paper of the exposure meter is subjected, and subjected *before* the exposure is made, and therefore to some extent different from the light *during* exposure. This variation is often far greater than that of the standard candle. The error of judgment as to when the tint of the paper is the same, or equally dark as the standard tint, is also open to considerable error. My position is that, in spite of the many sources of error to which both instruments are liable, they are both valuable indicators of correct exposure when carefully used and with properly determined constants.

When using the meter, Mr. Watkins advocates the use of different subject numbers for objects of light, medium, or dark colours; I do not see the propriety of so doing where the nearest possible approach to correct representation is aimed at. Let us suppose three houses; light, medium, and dark. Let the medium house require subject number 100; if not, paint it so as to require this number. In like manner, let the other houses be so light and so dark, respectively, as to require subject numbers 50 and 200. Can these three houses be correctly represented on one plate? If not, the subject numbers fail to help us, as does the actinograph; neither instrument can help us to photograph an unphotographable combination. Can they be correctly photographed? Then *one number* must serve for all three. I always use the No. 100 for such compounds of light and shade as are ordinarily met with in views, and find the result practically correct.

The cases where the subject numbers 200, 300, or more are mainly applicable, say the photographing of dark interiors, paintings, &c., are cases where the actinograph is evidently unsuitable; and an argument against the actinograph under such circumstances is like saying that a sun-dial will not work by moonlight, which everybody knows.

I do not quite follow Mr. Watkins' suggestion to use a Spurge's sensitometer, to determine the speed of plates. As I gather, he would expose a plate behind the instrument for a certain time to a standard illumination, develop, and compare with a plate of standard density. Suppose that, in one plate thus treated, the portion exposed behind hole No. 4 matched the standard tint, and that in a second plate the portion behind No. 9 matched the standard tint. What inference would he draw from this experiment? That the speeds of the plates are inversely as the areas of apertures? From all I know of the action of light on the photographic film, I doubt whether this would be a correct inference; indeed, unless I am entirely wrong, this inference is baseless. No conclusion can be valid from such restricted observations. The behaviour of the plate to many varying amounts of illumination must be studied before a correct verdict as to the rapidity of the plate can be pronounced. We have to find the first term of a series of illuminations, ever doubling, in which the densities of deposit increase, approximately, by equal differences. That only can be the real criterion of the rapidity of the plate; the actual density of any one portion is no guide whatever.

I see, from a subsequent letter of Mr. Watkins', that he makes use of Captain Abney's photometer. Would he be so good as to inform me what is the exact meaning of the numbers denoting the transparency of a film with that instrument? Mr. Channon supposes them to be percentages, though, as Captain Abney quotes numbers higher than 100, this can hardly be the case. I have tried to ascertain what they really are, but have not succeeded.

I presume that they are the same numbers as Mr. Watkins' uses to express opacity in his letter of May 28.—I am, yours, &c.,

Ash Club, Manchester, June 6, 1892. R. C. PHILLIPS.

"COSMOS."

To the EDITOR.

SIR,—"Junior" concludes his letter of the 4th with an impeachment of my credibility. For him the terms "not long ago" and "several years ago" are of a sufficiently contradictory nature to warrant an insinuation of untruthfulness. This eagerness to convict me of falsehood scarcely indicates an honourable opponent's disposition or desire to entertain an explanation in maintenance of my veracity, and I therefore propose to leave your correspondent undisturbed in his persuasion to the contrary. Everybody, however, endowed with ordinary intelligence (among which class "Junior" restrains me from including him) understand

quite well how easy it is in writing and speaking to misuse such phrases as he picks out, as well as many others of an equally inexact character; and consequently are above the paltriness of converting pardonable vagaries of expression into evidences of prevarication.

I am puzzled to understand why my anecdotal reference to the snubbing with which the younger members of a photographic society I formerly belonged to (probably when "Junior" was in long clothes) were treated by their seniors, should be taken to apply to the London and Provincial Photographic Association, of which I do not claim membership, of whose discussions my knowledge is simply gained through the reports in your pages, and to my presence at whose meetings a residence nearly two hundred miles from London would be an obstacle. In denying assertions which were not applied to his society, your correspondent gives such a sorry exhibition of mingled impetuosity and stupidity that I am surprised at his possession of the flash of wisdom which led him to withhold his name and thus spare him the ridicule of his fellow members. I never "supposed" that the junior members of the Association were snubbed week by week, and even "Junior" himself cannot put his finger on such a supposition either implied or expressed, or why does he "deny the truth of assertions *if* applied to his Society?" If I supposed or asserted anything as to the Association why "Junior's" "if," and as I did neither, why his denial?

In accusing me of gibing and sneering at Mr. Haddon "Junior" is guilty of a piece of exaggeration as malicious as it is inexplicable. I appeal from the verdict of a judge whose bitterness of attack perplexes me by its total lack of provocation to the impartiality of any unprejudiced reader of this correspondence. Mr. Haddon's advice to amateurs to make collodion positives, as well for the reasons given as for others, may be excellent enough in the abstract; but, Sir, I ask, in all good faith, what earthly chance does it stand of being put into practice by modern amateurs? Mr. Haddon—whom I do not know, but whose contributions to photographic knowledge I have esteemed for many years—would probably himself be more surprised than anybody else to see his counsel taken. It was because I regarded his recommendation to amateurs to take up bath photography while dry plates hold the field as so much waste of breath, that I ventured, good-humouredly I submit, to ridicule the advice. In so doing I did not intend to exceed the limits of fair and legitimate criticism, and I don't think I have. I have no means of knowing whether Mr. Haddon takes an opposite view of my remarks, but if he does I trust he will believe that nothing was farther from my design than to "gibe" and "sneer" at him, a form of comment in which his impulsive young advocate seems to me to shine with a success I can never hope to emulate.—I am, yours, &c.,

COSMOS.

PHOTOGRAPHIC PRINTERS.

To the EDITOR.

SIR,—The interesting series of letters now appearing in THE BRITISH JOURNAL, *re* printers and the difficulties they have in finding employment, opens up a wide field for discussion. It is not only in the ranks of the photographic printer that there are causes for lamentation, but the operator, retoucher, reception-room attendant, and mounter and finisher, have also solid reasons for complaint against the tendency to employ the *cheap and nasty* order of worker. Salaries, as any one who is in the know is well aware, have been for some years now, on the downward grade. 1st. Chiefly because of the over-crowded state of the photographic labour market. 2nd. And of no less importance in its bearing upon bad trade generally, is the want of *proper respect* for their calling amongst certain classes of professionals; for, if these gentlemen who work on the "given away with a pound of tea" principle, *had* any respect for photography (or themselves) they would never descend to such means, nor would the "one cabinet and three C. D. V.'s for 2*s.* 6*d.*," and the "one 12 × 10 beautifully finished enlargement given with one dozen cabinets" fraternity pursue the (un)-even tenor of their ways without many a twinge of conscience. Of late years quite an army of cheap and nasty little dealers, retouchers and enlargers to the trade, have sprung up like mushrooms. These are the people who pander to the wants of the cheap and nasty amateur and professional, and to the semi-professional, who poses as an amateur, but who is a blackleg. Returning to the subject of the overcrowded labour market, it is overcrowded simply because it is glutted with the "Learnt it in six months!—can operate, print, tone; clever with children; salary, 25*s.* per week!" photographic wasters—the class of people who, having failed to become good tea-grocers' assistants, clerks, drapers, &c., &c., take up photography as a means of earning a livelihood. In conclusion, I say that if only employers had but the courage to keep up their prices, and be a little less apathetic to their own interests, they would be able to pay better salaries, employ better assistants, and therefore do better work, and instead of helping to drag photography through the mud, assist to place it on a higher pinnacle in the estimation of the public than it now holds. Again I say, employers keep up your prices, employ none but competent people, have nothing to do with the cheap and nasty order of dealer, and do not deal with those firms who do everything they can to catch the amateur at the expense of the struggling professional. I am, yours, &c.,

F. J. A.

June 14, 1892.

To the EDITOR.

SIR,—I have read with great interest the correspondence in your valuable paper "*re* Photographic Printers."

My experience has been similar to those already given in the pages of the JOURNAL.

Notwithstanding the fact that for some years I was connected with one of the principal firms in the kingdom, and possess testimonials of the highest order, I have found great difficulty in obtaining a permanent engagement.

The statement that good printers are scarce, and difficult to obtain, is not correct.

True, there are many duffers in the profession; but who is to blame? The photographer who, rather than pay a man a decent salary, engages a duffer at a very small salary; and because he does not prove a success, stigmatises the whole race of printers as bad.

Mr. Editor, printers have their grievances as well as those who employ them; and if photographers want good work, they must be prepared to pay a wage at least equivalent to that received by a bricklayer's labourer, not the paltry wage as at present offered.

Moreover, let them provide proper accommodation for a printer to do his work, and not push him into some out of the way corner, useless for any other purpose, and then complain if his work is not good.—I am, yours, &c.,

H. D.

June 6, 1892.

RED LIGHT AND THE EYESIGHT.

To the EDITOR.

SIR,—I notice one of your correspondents complains of his eyesight being affected through the use of red light in the developing room. Some time ago I was similarly affected, and no doubt, like many others, was almost colour-blind for some time. I, however, had a sheet of green glass running on rollers, and when the work was finished, instead of changing immediately into strong light, I turned on the complementary colour, and after a few moments found my colour-sight restored, and felt so much benefited that I would like others to try it for themselves. I suppose, in the case of orange or yellow light being used, its complementary (blue) would have the same effect.—I am, yours, &c.,

OPERATOR.

London, June 8, 1892.

"AN OLD PRO.'S" WAIL.

To the EDITOR.

SIR,—I sometimes think we professionals are falling out, because of our modesty or want of asserting our position and rights. We have no trade union or guild, no badge, decoration, or letter to show ourselves accredited members of an honourable calling; and no means of keeping any from infringing what is our position or rights. We cannot get our goods at a special trade price from dealers; when we work to a middleman, we are sweated to get the lion's share; when another does jobs we could have done, while we pay rent, taxes and extra insurance, he is free of these and we have no redress. I see at a Liverpool society, where the members do everything photographic for pleasure and nothing for pay, one party did some thirty dozen films 10 × 8 on the Continent last season; and a gentleman is going to the Land of the Midnight Sun with some thirty-five dozen 5 × 4. A wonder to me, "Poor Pro.," how does this kind of thing pay? Could you put one up to the secret of their trade? We might go in to amateur it. There must be money somewhere. Can't you tell us how to get a bit of the meat, or, if not, a bit of the bone, for our old gums?—I am, yours, &c.,

AN OLD PRO.

June 14, 1892.

LIGHT CAMERAS.

To the EDITOR.

SIR,—Will you please tell me the weight of the lightest half-plate and whole-plate tourists' cameras that are made? The reason is, I am a carpenter and amateur photographer, and have just made a whole-plate camera which only weighs three pounds ten ounces. I have shown it to several friends, both professional and amateur, and they all say it is lighter, more rigid, and compact than any they have seen. The size outside is ten inches by ten inches.—I am, yours, &c.,

F. POLLARD.

31, *Pynlimmon-road, Hastings, June* 14, 1892.

[We must confess to not having scaled the various types of cameras extant with a view to discovering which boasts of being the lightest made, but a whole-plate that only weighs three pounds ten ounces is certainly extremely light.—ED.]

Exchange Column.

Answers to Correspondents.

All matters for the text portion of this JOURNAL, *including queries for "Answers" and "Exchanges," must be addressed to* "THE EDITOR," *2, York-street, Covent Garden, London. Inattention to this ensures delay. No notice taken of communications unless name and address of writer are given.*

*** *Communications relating to Advertisements and general business affairs must be addressed to* "HENRY GREENWOOD & Co.," *2, York-street, Covent Garden, London.*

T. K. (Darlington).—Thanks.

J. C. HUGHES, SCOTIA, E. W. A. S., and others.—In our next.

R. G.—Yes; the developer on bromide prints should be kept in motion.

R. D. SMILLIE & Co.—It is described in this JOURNAL for March 11 of this year.

MERCURY.—1. There is no frame on the market for printing wood-blocks. 2. We do not know what paper is most read by wood-engravers.

IMPROVER.—North America, as a field for photographic operators, is in no sense superior to Scotland; hence we do not advise you what part of the States to go to.

METAL.—Try the effect of diluting the ammonia with its own volume of water. To ascertain when fixation is complete, test successive ammonia baths until no silver chloride is precipitated.

W. JOY.—Saxe paper is to be had in continuous lengths of about four feet six inches wide. But we do not know where it is to be had in small quantities. It is usually sold by the roll, weighing a hundredweight and upwards.

J. KNOWLES.—It is quite impossible for us, or any one else, to say, by simply looking at it, if the mount contains anything that would act injuriously on a photograph. It can only be ascertained by a careful chemical examination.

S. KARL asks: "If a thing is patented—say, a detective camera—can I make (legally) one for my own use? Of course, I know I must not make for sale."—It is illegal to pirate a patented invention even if the article is not made for sale.

EXPERIMENTALIST.—For a lens of the rapid type, of one and a quarter inch diameter, we should much prefer a prism to a mirror for taking reversed negatives. With lenses of large diameter, the mirror is to be preferred on account of the cost.

A. E. F.—The pictures are, on the whole, very good, but would have been improved by a little less exposure, and printing on a better sample of paper. The lighting of one is rather poor. With a little more practice, you should meet with fair success.

R. B. Y.—If the lens be symmetrical, it does not matter which combination be used as a single lens. Arrange the convex side so as to be next the ground glass. The stops, as fitted in the tube, though not being in the *best* position, will answer every practical purpose.

H. J. D.—Yes; white, hard varnish, thinned with methylated spirit, is often used for varnishing negatives. It is not so durable as "brown hard," as it is more liable to abrasion with rough usage. The slight colour in the thin film of the latter varnish will practically be of no disadvantage.

P. McN. asks if any one is allowed to take photographs of any of the ancient statuary in the British Museum.—Yes, by first obtaining permission of the authorities. Make formal application, by letter, addressed to the chief librarian. It will be well to state in the application the purpose for which the photographs are required.

BERKS.—The prints forwarded are very pretty lane studies, but we think the negatives have very little, if any, commercial value. Berkshire lanes are very like the lanes of most other counties. You might, however, submit copies to some of the publishing houses, such as Poulton & Sons, Lee, or Frith & Son, Reigate. They would be the most likely purchasers of the negatives.

C. M. MOSES.—We can scarcely imagine the negatives blistering, at this season of the year, directly the developer commences to act, unless the developer or the water with which it is made had been exposed to the heat of the sun; moreover, we have never heard of blistering with the brand of plates you are using. Make another trial. This time be sure that the developer is of the normal temperature.

BENJAMIN C. asks the best material with which to coat a large wooden trough that is to be used for silver solutions for sensitising paper?—One of the most inert materials, and, at the same time, one of the best waterproofers, is paraffin wax. Before applying it, the wood should be made perfectly dry and warm, indeed hot. Expose the vessel for a few hours to the heat of the sun's ray, and then apply the wax in a fluid condition evenly with a hot iron or spatula.

MIDLANDS writes: "I have a very strong impression that a photographer in our town is sending out bromide prints for platinotypes, although he charges for the latter, and at a high figure too. Can you tell me how I can test one of the prints to see, for certain, by which process they were made?"—There is a very simple test. Immerse the suspected print in a solution of bichloride of mercury. If the print be a silver one, the image will be gradually bleached; if platinum, it will be quite unaffected by the treatment.

R. BOTWRIGHT asks how reversed negatives, as regards left and right, are made for photo-mechanical purposes.—There are many ways of making them. They may be taken direct by means of a prism or mirror in front of or at the back of the lens; or the sensitive plate may be placed in the dark slide reversed, and the negative taken through the glass, which, of course, must be clean on its surface; or the film may be stripped from the glass by Plener's method with fluoric acid. There is yet another way. The negative may be reproduced in the camera, either the transparency or the negative being reversed in the copying. All these methods are constantly being employed. There are others, however.

S. BLOUNT complains that when making, or rather attempting to make, lithographic transfers, for transferring to stone, he cannot get the transfer ink to leave the paper clean when it is treated with the warm water. He says he can get the ink away by rubbing somewhat hard, but it leaves the paper dirty, which soils the stone, and wants to know the reason.—As he does not say how the paper is prepared, or the kind of ink employed, it is difficult to reply. Presuming, however, that he uses the paper and ink sold commercially for the purpose, the reason may be that the paper was kept too long after sensitising, or that the ink was used too thick. A very prolific cause of this trouble is when unsuitable negatives are employed. Unless the negative is specially suited to the work it is impossible to obtain clean transfers.

A. PHILLIMORE complains that he has several lots of sensitised paper that he has purchased lately, but upon none of it can he get a rich, deep tone. He says: "Before they reach that stage they become woolly, and, after they are fixed, they are like the colour of mud. It cannot be the fault of the negatives, as when they are printed on ——'s paper I get just the deep tones I desire. But there, that paper is dear. Can you give me a word of advice?"—If the negatives will yield rich tones with some papers, it is clear that they cannot be blamed. Some papers, however, will not tone beyond the warm brown stage, though they will yield good prints of that colour. We can only suggest that our correspondent be content with that tone until the paper is used up. Then procure a supply of that which gives the tones desired.

A. W. FARLEY complains that rain, by coming through the roof of the studio, played sad havoc with his backgrounds, &c., all of which had been recently redistempered for the coming season, and now have stains where the water has trickled down. He asks what is the best to be done, as he does not wish, if it can be avoided, to have to go to all the expense over again?—We fear there is now no remedy. If the evil is discovered at the time, stains may often be obviated by making the background evenly wet all over, and then allowing it to dry spontaneously. The only thing we can now suggest is to make the backgrounds, or, by way of experiment, one of them, thoroughly wet, and then work it well and evenly all over with a soft whitewash brush, and then set it aside to dry. Sometimes this treatment will get rid of this kind of stain, but not always. Anyhow, it is worth the trial.

P. O. M. says: "A few months back I sold a number of local views to a visitor to the neighbourhood. He had them mounted and bound up as a folio by a bookbinder. Now all the prints are fading, and he wants me to replace them, threatening if I do not that he will sue me not only for the value of the prints, but for the cost of the book as well. As my own prints, mounted and unmounted, made about the same time, show no signs of fading, I suggested that the mounting material or the boards were the cause of the fading. I have just ascertained that the prints were mounted with the ordinary paste used in the workshop. What would you advise?"—We should say, Resist the claim. If paste such as is used in some workshops is employed for mounting photographs with, there need be little wonder at their quickly fading. If our correspondent can prove that a deleterious mountant was used, it will be a good defence to an action.

LONDON AND PROVINCIAL PHOTOGRAPHIC ASSOCIATION.—June 18, Outing down the River. First boat after two from London Bridge. 23, *Intensification.* 30, Annual General Meeting.

PHOTOGRAPHIC CLUB.—June 22, *The Relative Permanency of Prints by the Various Methods in Present Use.* 29, *Plate and Film-changing Appliances.* 18, Saturday outing down the River. Boat from Old Swan Pier at two o'clock.

SOUTH LONDON PHOTOGRAPHIC SOCIETY.—June 20, *Hand Camera Work*, Mr. James A. Sinclair. July 4, *Can our Excursions be made more Interesting and Useful?* Mr. J. F. Kelly. 15, *Photographic Dodges and Combination Printing*, Mr. J. Miller. Visitors invited.

KIMBERLEY CAMERA CLUB.—The annual general meeting of this Club was held on Friday, May 13, when the following were elected office-bearers for the ensuing year:—*President*, Rev. Father Ogle; *Vice-President*, F. Skead, Esq., B.A.; *Hon. Secretary and Treasurer*, Malcolm Macfarlane; *Council*, Messrs. C. A. Chappell, A. Gasson, and J. Henry.

GLASGOW PHOTOGRAPHERS' HALF-HOLIDAY.—Messrs. Turnbull & Sons' *employés* and friends had an outing on Friday last to celebrate the movement recently adopted in Glasgow. The party was under the care of Mr. John J. Moran, who was instrumental in bringing the half-holiday movement to a successful issue. The location was a charming spot on the Clyde—Inverkip; and the company, numbering over seventy people, indulged in games, dances, sports, and a visit to the beautiful glen, and returned home, after spending a most enjoyable meeting. The firm very kindly closed earlier than usual, so as to enable the *employés* to have as big a day as possible, which was much appreciated.

THE BRITISH
JOURNAL OF PHOTOGRAPHY.

No. 1677. Vol. XXXIX.—JUNE 24, 1892.

LONG-FOCUS SINGLE LENSES FROM RECTILINEAR COMPOUNDS.

A question frequently arises as to whether it is not possible to employ, for landscape purposes, one only of the two lenses that form a rectilinear combination. If the front lens be removed from the mount, and the back one alone left *in situ*, a very excellent landscape objective, of about double the focus of the combination, is obtained. When used in this way, the diaphragm will be found to be rather too close to the first surface of the lens, and, to ensure the best results, the distance between them must be increased. This is sometimes conveniently effected by placing a cap, pierced with appropriate apertures, on the outer end of the tube, from which the anterior lens has now been removed. It is occasionally done, too, by a supplementary ring screwed in the rear end of the mount, and into which the lens in turn is adapted.

It will be observed that this implies a very considerable lengthening of the camera, and it is often found, to the chagrin of the user, that the camera will not extend sufficiently far to admit of the subject being brought into focus, for it must be borne in mind that, although the focal centre—that portion from which, in a *combination*, the focus is to be measured—lies practically mid-way between the lenses, or at the centre of the tube, this is not the case when one of the lenses is to be used alone in the manner described, for now the focal centre is transferred to a point outside of the convex surface of the lens, and actually nearer to the ground glass of the camera than the lens. From this it will be seen that the prolongation of the camera must, in order to admit of a single component being thus employed, extend considerably farther than at first sight would be anticipated.

But what is to be done when no such distension is permissible? Although it is doubtless best to employ a single lens with its flatter or concave side to the object, it is also possible to use it when reversed. This is more particularly the case when, as in the instance before us, it happens to be a rather deep meniscus, for the components of lenses of the rapid rectilinear type are invariably menisci. If, therefore, instead of removing and laying aside the front lens of such a combination, we treat the back one in that way and leave the front lens itself in the mount, we shall find that not only do we get an image the same size as when the back lens was used, and that we get good bright definition on the plate with a moderate stop, but we also obtain these advantages with a distension of the camera less by several inches than when the back element of the combination is employed situated at the rear end of the mount. The precise amount we gain, or, in other words, the amount practically added to the extension of the camera, equals the entire length of the brass mount of the lens, in addition to the small portion intervening between the outer surface of each lens and the optical centre, which, as we have pointed out, is in such a case located outside of the convex surface. A camera, therefore, which would not expand nearly sufficient to permit of the employment of a single component of the combination when the back lens is in question, may frequently be utilised with entire satisfaction when the front lens, still remaining in its place, is used.

We know very well that a lens, when worked in this position, with the stop behind it, will not cover a large field so flatly as when in a reversed position; but, when employed, as it must be, with a stop, it will cover with considerable brightness and sharpness a field at least as large as that covered by the combination, even when well stopped down.

Of late we have employed this system to its full extent. Two of our cameras, one of them a 10×8 and the other a $6\frac{1}{2} \times 4\frac{1}{4}$, possess a distending range which, while considerably in excess of that required for the combination lenses usually employed, yet fall short of what is requisite when the single half of any of them is employed in the old way. But by adopting the method now suggested—and it applies to both of the cameras in question—an enlarged view, the objects being double the size of what can be obtained by the combination, is now got with the greatest ease, and with from half an inch to an inch of camera distension to spare.

We need scarcely point out that many of the two compounds forming the lenses of the rectilinear and symmetrical are not absolutely indentical one with another, the back lens being frequently shorter in focus than the front. In this case it only remains for the photographer to select the particular combination of that focus which coincides approximately with the length of the camera draw.

FACTORS IN EXPOSURE.

Mr. Howard Farmer's communication to the London and Provincial Photographic Association, on *Some Prime Factors in Exposing*, appears, from the tenor of our report (see page 413), to have been marked by considerably more information of a nature likely to be of service to the inexperienced photographer in an admittedly difficult branch of his subject than most dissertations upon exposure with which from time to time we are made acquainted. Suggestive as well as practical, his examination of the numerous factors which have to be considered in the exposure of a plate should serve as a useful auxiliary to those who need reminding of the many causes which directly influence that important operation. There is an oft-quoted remark of Captain Abney to the effect that development is an art and a science combined; but, if this is meant to favour the

belief that the successful treatment of the developable photographic impression is attended by difficulties which only assiduous study and practice can surmount, we incline to think that the dictum is more applicable to exposure than to development.

Starting with the proposition that the correct exposure of a plate under normal circumstances is to be ascertained by calculations which take cognisance of the factors involved, several modern inventors have produced actinometrical instruments and exposure tables of undoubted ingenuity which it is claimed will, by proper use and application, relieve a photographer of the difficulty of arriving at the duration of his exposures entirely unassisted. In these mechanical and other devices, however, by no means all the factors involved are always given play, and they are thus open to considerable theoretical, if not practical, objection on those grounds. Besides the light, the aperture of the lens, and the rapidity of the plate, subject, colour, and distance also claim entrance into the calculations, although they are not always included; and since, so far as we are aware, no accurate rule is available for estimating the values of light and colour, to say nothing of subject and distance, in relation to lens apertures and plate sensitiveness, all mechanical aids to exposure must of necessity exist under the disadvantage of comparative imperfection.

This, of course, excludes the faculty of judgment from the calculation; but the quality of judgment in photographic matters varies immensely with the individual, and in no respect more so than in the case of the exposure of the plate. We have noticed, indeed, that in the employment of mechanical aids to exposure the photographers most successful are usually those whose accuracy of judgment has been confirmed by long experience in the art of unassisted exposure. Again, there have been to our knowledge instances of exposure by meter and exposure by judgment being made, and, all other things equalised, with the results that the exposure by judgment was correct, and exposure by meter plus the requisite judgment markedly incorrect.

The *raison-d'être* of mechanical aids to exposure, if invisible to experienced and finished photographers, is, nevertheless, obvious enough. They are designed to remove from the path of the beginner the difficulty of arriving at the correct exposure of his plate. Their success in bringing about the attainment of such a result depends to an almost total extent upon the skill of the individual in putting them to practical use; but, as we have already pointed out, the majority of the factors are not constants, and, besides, are not accurately determinable on emergency, so that the sources of error other than those referable to the variability of the personal equation are not to be overlooked. The speed of the plate and the power of the light may be ascertained strictly according to rule, a given aperture of lens employed, and a certain duration of exposure indicated. But the influence of distance and colour of subject, as well as atmospheric perspective, that we wrote of a few weeks ago, and momentary variations in the power of the light, are of necessity left to the photographer himself to determine, and, if he be immature or inexperienced, it is hardly necessary for us to point out that the opportunities for error and false judgment are ample. Indeed, we are not sure that in the majority of cases the probabilities of errors of judgment are so great that the accuracy of the constant factors is more likely than not to be effaced, and thus the superiority of mechanical aids to exposure over the unassisted judgment is not sustained.

In classifying methods of exposure in vogue under several heads, Mr. Farmer seemed to think that, where the exposure was simply judged by experience, no method could be better if the experience was sufficient. At the same time he remarked that, for a young beginner or the student, the method was practically useless. So much the worse for the beginner or the student. The indefinable quality in a clever photographer which enables him to judge of his exposures with such accuracy that, as we are aware is the custom of many, he never makes a second exposure on a subject, may conceivably be acquired by rule; but, having regard to the necessary inconstancy of some of the factors, we are sceptical on the point. The modern fever for reducing certain branches of photography down to the level of mere mechanics is an unhealthy one, as it substitutes the cut-and-dried determinations of the arithmetician and the calculator for the deeper and more lasting wisdom of experience.

Experience indeed seems about the last thing in the world which many consider to be essential to the training of the modern photographer; hence exposure meters and tables. But, in times when such things did not exist, experience was the only path to success in exposure and other branches of photography, and on the whole neither we nor the old race of photographers themselves have any cause to lament that there was then no royal road to correct exposure. Photographers—and amateurs at that—were content to learn by their failures; nowadays the chances of failure are intended to be reduced to the minimum for them. It is possibly a very unscientific thing to advise a young photographer to acquire a knowledge of exposure by the appearance of the image on the ground glass added to a studious adherence to a suitable brand of plates and a standard developer; but we are almost tempted to do so when we reflect upon the many skilled photographers, professional and amateurs, who have acquired that knowledge by no other means, and who at the present moment are doing irreproachable work on the same rule-of-thumb basis.

Without denying that exposure metres and tables are in certain respects useful, we cannot but think that the acquirement of experience in the old-fashioned way, even though it takes a year or two, is more likely to impart to a beginner a knowledge, judgment, and mastery of exposure, which will enable him to work with a high degree of accuracy and certainty, than even a theoretically and practically perfect actinometer would do. The former may be difficult to obtain, the latter is nearly impossible; and, were it not so, it would not diminish our belief that, after all, the cumulative lessons to be learned from the growth of success out of failure are of considerable educational value to the young photographer. Remembering to what a large degree the qualitative character of the negative relies upon the exposure, no pains, it seems to me, should be too great to exert in studying this branch of photography, and to that end no system, in our opinion, is superior to that of trial and error, which, though it may be tedious, is never uninstructive.

ESTIMATING CHLORIDES.

Scarcely a year passes by without our having to chronicle some new method of recognising or estimating the halogens when associated in a mixture. Many of them are too intricate for the unskilled chemist, others may be undertaken with care by the comparatively inexpert. Some time ago a method for determining iodine in presence of chlorine or bromine, having

for its underlying principle the slight solubility of the yellow colour of thallous iodide, was given by Herren Hübner, Spezia, and Frerichs. It was partly gravimetric and partly volumetric, and was too involved for ordinary photographic experiment; but Herren Jannasch and Aschoff have proposed a new method of separation, which would lend itself readily to photographic investigations where, for example, it was desired to ascertain the amount of chloride present in a particular dry plate. The method proposed for separating iodine and chlorine is by means of thallium sulphate, which gives an absolutely insoluble precipitate of thallous iodide in cold water containing alcohol, even in presence of ammonia and other compounds in which thallium chloride remains in solution. Unfortunately, however, the bromide cannot be separated at the same time, as the thallous bromide is soluble.

Last Year's Sunshine.—According to the report of the Astronomer Royal at the *Annual Visitation of the Greenwich Observatory*, the amount of sunshine recorded by the Campbell-Stokes Recorder, and after rectification, was 1222 hours, which is about sixty-six hours below the average of the preceding fourteen years. The actual time the sun was above the horizon was 4454 hours. It is thus seen that we had twenty-seven per cent. of possible sunlight, or between five and six per cent. below the average.

The Convention.—We have received the complete prospectus of the forthcoming Convention at Edinburgh. It is issued in the form of a small pamphlet, and gives a list of members of the Council, of the Local Committee, with details of excursions to various places of interest, and a mass of general information, which will be of considerable service to those attending the meetings. In addition to the foregoing the tariffs of the principal Edinburgh hotels are given, as well as a synopsis of the formal proceedings of the Convention during the week commencing July 11.

Coloured Lantern Pictures.—Methods by which blue lantern slides may be produced have recently been published, but surely the carbon process would be the simplest way of all. We well remember some brilliant blue lantern slides being shown on the screen at one of the lantern exhibitions of the old South London Photographic Society, many years ago, if we remember rightly, by Mr. Foxlee. Now, by the carbon process, transparencies may be produced in almost every conceivable colour, and that by the simplest means. If a demand existed for coloured "carbon" tissues, a supply would doubtless be forthcoming. The colour of any carbon transparency can be greatly modified by toning or dyeing it, as we have explained on former occasions.

A New Antiseptic.—As we cannot be supposed to have arrived at the production of a perfect antiseptic harmless to photographs, it is worth noting that a new aspirant for honours in this direction has made its appearance. Formaldehyd is stated to possess remarkable properties of sterilisation, which practically amounts to the same thing as being antiseptic. It is so powerful in its effects that it is stated that when so readily putrescible a compound as urine is treated with it no putrefaction can take place. In some of the preparations used in bacteriological research its effect is more powerful even than corrosive sublimate, one of the best antiseptics known, but objectionable on account of its toxic properties, and quite inapplicable to photographic purposes on account of its chemical action.

Photographing near Foreign Forts.—Photographic tourists have before now subjected themselves to considerable inconvenience through erecting their cameras in proximity to Continental fortifications (although the latter have not been visible from the spot), not knowing that they were doing wrong. The term "near" is a very elastic one with some over-zealous officials abroad; but it cannot be surmised that, when stretched to its utmost, it can exceed a mile or two. Now, it often happens that some excellent views might be obtained from this forbidden ground, and made more interesting on account of the interdiction. How about the new tele-photographic lens? With this instrument and the clear atmosphere of the Continent, distance becomes ignored. Reversing a well-known phrase, it may be said, "Yet so far, still so near."

Difficulties in Making the Great Star Map.—The attempts to secure the required uniformity of stellar magnitudes on the photographic plates by the employment of the metallic gauze screens of one definite mesh were unsuccessful. Much time was consumed (at Oxford University Observatory) in the experimental research into the action of such screens on the photographic image, and in the course of the inquiry certain unexpected and interesting results came to light, the substance of which was communicated by Professor Pritchard to the Paris Academy, and which were subsequently published in the proceedings of that body. The result has been the production (and the distribution by the Paris Academy) of photographic catalogues of stars of the ninth and eleventh magnitudes within small specified areas for the use of the eighteen observatories engaged in the international chart of the heavens.

Munich Fine Arts Exhibition.—A few weeks back we alluded to this international Exhibition as being likely to prove a great success. It is now open, and is a very fine one. There are upwards of three thousand frames. The pictures are from almost all parts of the world, though we are given to understand Great Britain, numerically, is not well represented. This may possibly be, in a measure, accounted for by the fact that the Royal Academy has a greater attraction for British artists than a foreign Exhibition. Some photographs are shown, but it appears they are copies of architectural designs, &c. The illustrated catalogue, a copy of which is now before us, is well got up. It contains about a hundred and fifty illustrations of the more important works, including statuary. The majority of the illustrations are from half-tone process blocks, which serve well to show the present state of this branch of photo-mechanical work in Germany, when applied commercially. We are told that the catalogue, like most others, for that matter, had to be got up in a hurry. It is a marvellous two marks' worth. Those visiting South Germany this summer should make a point of seeing this Exhibition.

A New Permanent Incandescent Lamp.—One of the drawbacks to the use of incandescent electric lights is the ultimate loss of light, owing to the gradual covering of the inside of the globe with a fine coating of black, derived from the slow conveyance of particles of the carbon filament to the surface of the glass. According to an article in the *Electrical World*, a new method of exhausting the bulbs has been devised, and is now in use, which quite prevents the occurrence of this blackening. The usual way of exhausting the globe, which, as our readers are aware, is a necessary part of the manufacture, is by means of a mercury pump. With the new pump, which was finally made a success on May 9, 1890, mercury is not used. It makes a more perfect vacuum than the mercurial pump, and does the work more quickly. The pump in use by the *Beacon Vacuum Pump and Electrical Company* can exhaust 600 lamps at one time, while the other cannot make as good a vacuum in five hours on six lamps. Furthermore, the residuum or vapour of mercury in a globe exhausted with mercury is injurious to the filament. It will likewise blacken the interior walls of the globe as before mentioned. With the new pump a remainder of vapour of oil or hydro-carbon is left, and it will decompose in about twenty-five hours, leaving a perfect vacuum behind. Hence the lamp will not blacken, as the small particles of carbon from the filament will have no carrying medium to convey them to the glass.

Restoration of Faded Prints.—A great deal of thought and experiment have from time to time been expended on the attempt to render silver prints permanent; to what effect, in practice, alas! we know but too well. However desirable it is to secure stability in the photographs of the future, it is equally so to be able to restore those that have faded; or, at least, those of departed friends, or such pictures as cannot be taken again. Little experiment seems to have been made in this direction, or, if made, the results have not been published. The material that once formed the image, it must be assumed, still exists in the paper, though in an altered state, as it has not yet been proved to be volatile. All that is wanted is a method for restoring this to its original condition. The question is, What? It has often been stated that a faded silver print can be restored by treatment with bichloride of mercury. This is a fallacy. By the treatment the sickly yellow tint is removed, and the print becomes brighter, but no detail that has actually disappeared is restored. Still, in many instances, the picture is considerably improved in general appearance. *Apropos* of this subject, many of the pictures "restored" with the bichloride have an unpleasant red tone. This may, however, be avoided by employing a much weaker solution, and allowing longer time for its action. A solution containing from a quarter to half a grain of the salt to the ounce of water with several hours' immersion is better than a stronger one and a shorter treatment.

Photography and the General Election.—"It is an ill wind that blows no one good," says an old proverb. A General Election always brings with it a stagnation of trade, except in some few businesses, and amongst these is, or ought to be, photography. During the last one or two Elections, some of the candidates for parliamentary honours have made it a feature to send their portraits with their canvassing cards, and in some instances, it is said, with good effect. Now, the forthcoming Election ought to bring a good line to a large number of portraitists, especially to those in the provinces who are enterprising enough to secure the advantage of supplying the electors with portraits of the candidates. Of course, the local photographers would be the only ones who would obtain the commissions, as it would only act adversely to the would-be member to have the orders executed out of the district. The question will arise to many as to how the orders are to be executed, as, after they are given, the work is usually wanted in a very short time, insufficient to permit of silver printing. Amongst the mechanical processes available, we have collotype, Woodburytype, and process blocks, all of which are good for the purpose. There is yet another process which is often overlooked where rapidity of production is necessary, we allude to bromide paper. With this and a single negative it is possible to produce several thousand prints within twenty-four hours, as there is no mould to make, or plate to prepare, before printing can be commenced. What can be accomplished with this method has been fully exemplified in the illustrations in our ALMANAC during the last few years. As we have just said, the Election ought to stir up business with many portraitists.

CHLORIDE PRINTING-OUT PAPERS—COLLODION AND GELATINE.

IN consequence of the increasing popularity of the newer kinds of printing-out papers, and in spite of the fact that there are numerous brands on the market of the highest excellence, there is still a tendency on the part of many, both amateur and professional, to prepare their own, the operations involved being far simpler and more easily carried out than in the case of the more sensitive emulsions used for negative or enlarging purposes.

There have been published in your columns and elsewhere many formulæ, accompanied by the necessary hints and instructions, for the preparation of both collodio and gelatino-chloride emulsions and papers; but, notwithstanding the very full information already given, there still remain apparently some difficulties which many of the would-be workers have failed to master, and I propose therefore, in the present article, to endeavour briefly to smooth over some of those which have been brought to my notice. It is not my intention to give any definite formulæ—at least, in the course of the present article, as my remarks will, I think, enable any reader to easily adapt those already published to the slightly modified conditions of working which we shall describe.

I will deal first of all with collodio-chloride emulsion, as being the older preparation and the one which will be found generally easier of application by the amateur, whether for paper positives, transparencies, or opals, for all of which it is equally well adapted. The chief difficulties found in connexion with this form of emulsion are the structural character of the film it gives usually, the strong tendency of the sensitive film to leave its support, and, finally, the short period the average emulsion will keep in working order. These, one and all, depend mainly upon the same causes, and in removing one we are fortunately able to greatly mitigate, if not altogether to eliminate, the others.

The first difficulty, that of structure or inequality of the film, is more especially felt when the emulsion is used upon glass or opal, and is due, as you pointed out, in an article published some months back, almost entirely to the employment of an unsuitable sample of pyroxyline, combined with the acid nature of the emulsion. These causes combined to produce that quality of film known to old collodion-workers as "horniness," a condition in which the film itself is extremely tough and contractile, and, owing to the indifferent fluent properties of the emulsion, generally presents a series of crape-like ridges, which are extremely unsightly, especially in the case of transparencies. The same horny or contractile quality is, further, the cause of the second difficulty, that of the film leaving its support; the collodion itself has very little inclination in the first place to attach itself firmly to any kind of support, and under the action of water exhibits such a powerful tendency to curl or pucker, that the invariable result is a final separation.

Then, again, the want of keeping properties in the emulsion is not due to decomposition of the silver compounds, but a gradual curdling or clotting together of the solid constituents which eventually separate and leave the solvents perfectly clear. This result is not attained all at once, but the defect passes through various stages, in which the emulsion becomes more and more gelatinous, and less inclined to flow over the support, until it at last becomes entirely useless. Here, again, the fault lies almost wholly with the pyroxyline, and the usually acid character of the emulsion, though it may, and probably is, in many cases, intensified by the employment of unsuitable salts in sensitising.

The methods or formulæ ordinarily given for the preparation of the collodio-chloride emulsion consist in the formation of a chlorised collodion, chloride of calcium being usually recommended on account of its easy solubility. To this a large excess of silver nitrate is added over and above what is required to neutralise the soluble chloride, and finally a considerable proportion, often as much as three or four grains to the ounce, of citric acid for the purpose of forming the organic silver compound that is necessary to give vigour to the image, and also with the idea of making the emulsion keep. The conditions, in fact, considered desirable in order to form a good emulsion are chloride, together with citrate of silver and an excess of silver nitrate and of citric acid. The desired result, so far as quality of image, is certainly arrived at by the method indicated, but it is at the expense of the other good properties of the preparation.

In the first place, the employment of chloride of calcium is to be avoided, as, especially in the presence of citric acid, it not only forms a useless precipitate of calcium citrate, but it acts powerfully on the pyroxyline, destroying its solubility. The excess of citric acid behaves in the same way, this acid, more perhaps than any other, exhibiting that particular action. Besides this, it does *not* form citrate of silver in the real sense of the term, as is usually supposed, the whole of the silver not converted into chloride remaining in a soluble state, or nearly so. If a quantity of silver nitrate, such as would be used in the emulsion, be dissolved in water and a corresponding proportion of citric acid added, a perfectly clear solution is formed, containing possibly citrate of silver, but held in solution by the free nitric acid as well as by its own slight solubility in water. If the same additions be made to plain collodion, the result will be a slightly opalescent emulsion, which *sets* upon glass perfectly clear and

transparent, and when *dried* shows a crop of minute crystals just as a similar quantity of silver nitrate would do. This shows that in the formula referred to the citrate of silver cannot be present in its most useful form, but acts merely as so much free silver, while the whole of the large excess of acid is at liberty to exert its most baneful influence.

Next, with regard to the supposed necessity of free silver nitrate and of acid, I have proved by careful experiment that this is much exaggerated, if, indeed, such excess may not be wholly dispensed with. I have, in fact, proved by actual trial that an emulsion containing no free silver nitrate, or so little that it is practically absent, will give a rich, vigorous image, and behave in every way as well as, if not better, than one containing the regulation excess; and, further, that it may be rendered alkaline without destroying its good qualities, or bringing about the decomposition of the silver salts. The action of the alkali, however, upon the collodion soon destroys its power of suspending the silver chloride, and thus renders the emulsion useless; but the experiment shows that at least a large excess of acid is unnecessary in order to make the emulsion keep.

Now, if we take an emulsion prepared according to the usual formula, only for the sake of simplicity substituting chloride of ammonium for the calcium salt, and keep it until it reaches the extremely viscid stage and refuses to flow over the glass, the addition of a few drops of alcohol containing ten per cent. of aqueous ammonia, followed by a vigorous shake, will quickly restore its fluent properties; and, if the alkali be cautiously added so as to leave a very faint trace of acid still in excess, the emulsion will be found to have entirely regained its original good qualities, and will show no further tendency to thicken or clot together. When poured upon glass too, it will in all probability show a denser or less transparent film, though in this respect citro-chloride emulsions are always much thinner than those of bromide.

In this experiment we have taken up the free acid by means of the alkali, and thrown down the citrate of silver as an actual precipitate. If the ammonia were added to a mixture of plain collodion with silver nitrate and citric acid without any silver chloride, the difference would be that the film when set would be opalescent instead of transparent, owing to the citrate being in the emulsified instead of the dissolved state; and in that condition it would only seem reasonable to suppose that it would perform its duty more effectually.

Again, if the quantity of silver nitrate used in sensitising be reduced to just the theoretical proportion required to form the chloride and citrate without leaving any excess, it will be found that little or no difference is made in the vigour of the resulting image, though its colour, and possibly its gradations, will be considerably modified. These, however, are easily readjusted by varying the proportion of citrate and chlorine of silver, the experiment showing that the excess of silver nitrate is needless. With that removed, we lose one of the greatest enemies to the keeping quality of the paper or film, if not of the emulsion itself, for it stands to reason that the more free silver nitrate there is present, in contact either with the pyroxyline in the emulsion or film or with the paper support, the sooner a spontaneous decomposition is likely to show itself. The citrate of silver in combination with the chloride suffices to give the requisite vigour of image, while it is sufficiently soluble in the aqueous portion of the solvents to impart that richness of colour which it is one of the functions of the free nitrate to supply, while it is not sufficiently soluble to exert the injurious influence of the latter.

As for the practical application of the foregoing remarks to existing formulæ, the process is very simple, especially to such as are able to calculate out the various chemical equivalents, although even this is by no means absolutely necessary, as we shall show. In the selection of pyroxyline no special care is needful so long as an ordinarily good photographic sample is employed; but much of that in the market at the present day is fit only for enamelling purposes, or for making surgical collodion, and it is hardly requisite to say that my remarks do not apply to remedying the defects of such samples.

Let the collodion be made of moderate consistency, neither too thick nor too thin, bearing in mind that a thin collodion gives always a more even and structureless film than a thicker one, and that for use on paper all the vigour and richness that can be required will be given by a comparatively thin emulsion, though for transparencies one of greater density may be desirable. Let the solvents be of as high grade as possible—that is, as free from water as can be obtained—because this is a condition that, more than anything else, operates upon the fluency of the emulsion and the character of the film. The larger the proportion of water the less easily will the emulsion flow, and the greater will be the tendency to "crapiness" and structural markings. As it is absolutely necessary to add a certain quantity of water in sensitising the emulsion, the importance of starting as free as possible will be recognised.

In selecting the salts, avoid those whose bases form insoluble citrates or other salts, as these are liable to combine with and act upon the collodion, causing partial or general insolubility. Perhaps nothing excels ammonium chloride, which, with the assistance of a minute quantity of water, is easily got into solution in the alcohol if triturated in a small mortar. Next, instead of employing citric acid in the free state, use it in the form of an alkaline citrate, the potassium salt being best for the purpose, as being the most stable. The chemically qualified reader may analyse the original formula, and, if possible, calculate the theoretical quantity of citrate to use; but it is scarcely worth the trouble, as the emulsion made in the ordinary way is an extremely indefinite compound. The better plan will be to make a trial by converting definite proportions of silver nitrate into chloride and citrate respectively, and, if the first be not satisfactory, to vary the proportions until the desired result is attained. Two parts of chloride to one of citrate of silver will form a useful base to start from. The citrate of potash may be dissolved and added to the collodion simultaneously with the soluble chloride.

The next question is that of acidification, and here I have only to say that, though it is not absolutely necessary for the keeping of the emulsion, it may, nay, undoubtedly is, useful in preserving the whiteness of paper after coating with the emulsion. But, in place of citric acid, I recommend the use of acetic, in the proportion of, say, a quarter of a minim to the ounce of emulsion. It may be conveniently added in the form of an alcholic solution of definite strength.

As regards sensitising, let the quantity of silver nitrate be such as to barely neutralise the chloride and citrate employed, bearing in mind that the citrate of silver formed acts the part of "free" silver. The nitrate is added to the collodion in the usual manner in alcoholic solution, formed by dissolving the crystals in half their weight of water, by heating in a test tube, and then adding a small quantity of alcohol, and again heating to ebullition. When formed into the collodion, and well shaken, the emulsion is complete.

Prepared in this manner, the emulsion will require to be kept a little longer before use in order to bring it into its best form; but, that stage reached, it will be found a far more permanent preparation than those hitherto in use, and to be free from the special faults we have already noticed. It is probable that the proportions of the various ingredients will have to be considerably modified in order to secure certain favourite colours of the image, though, after all, the original colour makes very little, if any, difference in the toned print.

A final hint may be given in connexion with collodio-chloride. A difficulty is experienced by many in coating paper, the usual plan being to pin it down on to a light board; but this generally involves a lot of trouble in covering corners and edges. Nothing is easier and more effective for small sizes, and it seems equally available for large than the following plan, heterodox as it may seem: Thoroughly wet the paper, and, when at full stretch, squeegee it on to a sheet of glass. Then, having carefully surface-dried it with a soft linen cloth, coat in the ordinary way, and, contrary to what might be supposed, the film will be as structureless and adhere as well as, or even better, than if coated dry.

W. B. Bolton.

(To be concluded.)

AMERICAN NOTES AND NEWS.

American Visitors to the Convention.—We have recently had the pleasure of a visit from Dr. Charles L. Mitchell, of Philadelphia, who must be known to many of our readers by his contributions to American photographic literature. Dr. Mitchell is to

read a paper before the Convention on the *Use of the Colour Screen in Landscape Photography.*

"Linen Bromides."—We read that linen sensitised with gelatino-bromide of silver for printing purposes has just been placed on the market by an American house. The advantage of fabric printing by development over the platinum and chloride of silver printing-out processes is not apparent, and we should be inclined to doubt its practical success.

Litmus Paper.—A note in the *St. Louis and Canadian Photographer* states that blue litmus paper is prepared from a seaweed, the common rocella, which is found in all tropical seas, but particularly and abundantly in the Mediterranean. It is a lichen which grows on the rocks in the water and near the shore. The litmus is prepared by macerating the plant in water with lime, potash, and other materials, and leaving it for weeks until fermentation ensues. When it ferments it first turns red, and then blue, and when the whole mass is of the proper blue colour it is pressed into a mould and made into small rectangular cakes, which have the look of indigo and the smell of violets. To make the litmus paper, an infusion of the litmus is made with boiling water, and unsized paper is soaked in it, being afterwards dried.

Storage of Albumenised Paper.—Mr. A. W. Clark says that "albumen paper, kept even for a short time in a close, warm room, will become so dry and horny that, although it may appear to take the silver properly, it is not in the proper condition for producing the best prints, even should no ill effects show until the toning is reached. Here trouble will make its appearance, and the toning is arrested, or, at least, but poorly accomplished. The paper requires only little damping, but requires time, according to its dryness, to absorb the proper amount of moisture." Mr. Clark believes that albumen paper still holds the fort, and is destined to do so for some years to come, and he has recently come across several failures in printing which he has traced to the albumenised paper having been kept in too dry a state before sensitising.

Toning and Fixing Gelatino-Chloride Paper.—Mr. Louis Bradfisch, an experienced manufacturer and user of aristotype papers, is convinced, in *Wilson's Photographic Magazine*, that the proper manipulation of these papers is by separate toning and fixing. After washing, he recommends a toning bath of gold chloride, soda acetate, and soda bicarbonate, and, when toning is complete, a combined hardening and fixing bath, which should be freshly prepared every day, and consists of forty minims of acid sulphite of soda solution (? strength), and two ounces of powdered alum in twenty ounces of water, to which two ounces of hypo are finally added. On immersion in this bath, the prints turn yellow, but assume the proper tone in from five to ten minutes.

Do Plates Increase in Sensitiveness by Keeping?—In an American contemporary, Dr. Vogel quotes Herr Wolf, the Heidelberg astronomer, in support of the theory that gelatine plates increase in sensitiveness by keeping. Herr Wolf says particular care is necessary with fresh plates. When formerly he received plates from the manufacturer he always observed that the new plates were not as sensitive as the previous ones, and that he had to expose much longer than before, so that it almost appeared as if the plate-manufacturer was turning out inferior goods. Last winter new plates of ——, with even three times the exposure, hardly showed the objects on the negative, which were distinctly visible on plates received in a previous shipment. He could not obtain, for instance, with three hours' exposure, those stars and nebulæ which previously he had photographed with the greatest facility in one hour. It was, he says, known to him before that plates change their sensitiveness somewhat, but that they would increase to three times their original sensitiveness he could not expect. The same plates which, in the beginning, had so little sensitiveness became as sensitive after five months as the previous ones, and surpassed all his other plates in sensitiveness. The orthochromatic plates seem to be less subject to this change of sensitiveness. According to Dr. Vogel's opinion, the gelatine here plays an important part. Lately he had to examine quite a number of different kinds of gelatine. Ordinarily they give emulsions of high sensitiveness only if ammonia is applied after cooking. He found only one kind of gelatine which, by cooking alone, gave just as sensitive emulsions as with ammonia.

Photography at the World's Fair.—The following petition to the Ways and Means Committee of the Columbian Exposition is being extensively signed on behalf of the American Photographic Societies:—"Having learned that it is the decision of your Committee, and that of the Executive Committee of the World's Columbian Exposition, that the granting of special permits to amateur photographers and others for the privilege of photographing in the Exposition grounds is to be refused, because they will interfere with concessions to be held by three or four professional concerns, we, the representatives of the photographic clubs and societies of the United States, do most urgently petition you to reconsider your decision; first, in behalf of the thousands of amateurs and others who will wish to exercise the right to photograph; second, because their work will make a far more valuable and complete record of the Exposition than is possible by the few to whom it is proposed to grant the privilege; third, because it is probable a larger revenue can be derived by the issuing of special permits to the estimated hundred or two hundred thousand photographers who will certainly visit the Exposition (at the rate of five dollars for a limited period of one week, aggregating very nearly half a million dollars), than will be realised by restricting the privilege to a few for a specified amount (which is likely not to be much above one hundred thousand dollars), while at the same time greater general benefit will accrue to all concerned. We hold that, as the camera is now so universally used by the public, and as the Exposition is a public enterprise, conducted by the United States for the public benefit and education, it is unjust to the public to restrict the photographic privilege as is now contemplated, when the same revenue can be effected by methods which will confer pleasure and instruction to an immense number, and with less friction. We earnestly request that the interests of the amateur photographers be especially recognised, because of the increased revenue they may bring to the Exposition, on the plan outlined, and on account of the great value of the work they will create. We further request that special facilities for photographic work be provided for the amateur on the Exposition grounds, from which an additional revenue can be derived above that previously mentioned." There is so much that is reasonable in the prayer of this petition that we hope the Committee will see fit to grant it; not only in the interests of American amateur photography, but also because we are certain a large number of the visitors from this side of the Atlantic will be accompanied by a camera, the use of which being interdicted must undoubtedly damage the Exhibition.

PHOTOGRAPHY AMONG THE LIBERAL ARTS AT CHICAGO.

In the regulations for the forthcoming (1893) Chicago Exhibition, we are told that "All the photographic exhibits, however, will be placed together in the portion of the Liberal Arts and Manufactures building allotted to the British Section." In spite of our having been recently told that photography is not art, it may yet be of some interest to inquire the meaning of the words Liberal Arts, seeing that it is in their company we are destined to find our photographs at Chicago. (Some may here lament that "adversity makes us acquainted with strange bedfellows.") Parker tells us that "the term Liberal Art is more venerable and famous than the term Fine Art." It is at least some comfort, then, that our companions have antiquity on their side! [For a note upon the term Fine Art the reader may refer to the BRITISH JOURNAL OF PHOTOGRAPHY, May 22, 1891, pages 323–4.]

It would seem that the name Liberal Art was, in its early usage, applied to a pursuit followed by one of free birth and cultivated taste, but subsequently its application became narrowed. The history of the term (according to Parker) seems to be somewhat as follows:—

1. The learned Roman, Varro (B.C. 116–28), is said to have written 490 books, a very large majority of which are lost, among them being

one called the *Nine Disciplines*, which seems to have been "an encyclopædia of science."

2. At some undetermined part of the fourth century one Martianus Capella wrote a philosophical romance, entitled, *The Nuptials of Mercury with Philology, the daughter of Phroneris*, in which the seven arts, grammar, dialectics, rhetoric, geometry, arithmetic, astronomy, music, appear as seven bridesmaids.

It is extremely probable that this was founded upon Varro's *Nine Disciplines*, the two missing members being architecture and medicine, the reason of their expurgation probably being because they tended towards the useful rather than the ornamental.

3. This composition of Capella's, who seems to have been a pagan, was apparently revised by Cassiodorus (A.D. 486–570). It seems that it was this Cassiodorus who again drew attention to these seven studies, and dubbed them "Liberal Arts;" but by that term he intended them to be regarded as sciences, and roughly defines them as those arts which are contained in books.

4. Johnson (*Idler*, No. 91) says, "There is, I think, not one of the liberal arts which may not be completely learned in the English language. He that searches after mathematical knowledge may busy himself among his own countrymen, and will find one or other able to instruct him in every part of those abstruse sciences." Thus, roughly speaking, the value of the term Liberal Art has not materially changed from the time of Cassiodorus to the present day.

It is here interesting to note that the early usage of the term has been evenly preserved in the Universities of Cambridge and Oxford, where the Bachelor, or Master of Arts, is supposed to have shown some proficiency in the liberal arts. There is reason to suppose that in the earlier days of these Universities music held a more prominent position than it now does. In both Universities, during the present century, there has been a marked movement towards placing the fine arts of music and painting (sculpture, &c.), in a more prominent position. The Slade Professors are growing in general appreciation.

In connexion with our twin term, Science and Art, it is interesting also to note that the earlier usage of *scientia*, *i.e.*, science, was practically restricted to theology. Many moderns have usurped this term, and would entirely dethrone the ancient sovereign.

Glancing back at the progenitors of the present-day liberal arts we may, without any violence of assumption, fairly well take stock of the legitimate descendants. From the first three bridesmaids of Capella are descended the ever-spreading family of the classics, including philosophy, philology, oratory (in law and politics), and kindred branches. From the next-mentioned three are derived mathematics generally, and its attendant younger branches, viz., the exact sciences, physics, chemistry, &c.; so that, corresponding to the present-day fine arts, music alone is represented, unless poetry may be smuggled in under the cloak of classics, and architecture, under the patronage of mechanics.*

Turning once again to the universities, it will not be difficult to see that the modern representative of music is more akin to this theory, *i.e.*, scientific side rather than to the artistic practice.

This is, *mutatis mutandis*, equally true of the usual instruction imparted by the Slade Professor of Fine Art, although of late years some encouragement has been given to the practice of music and painting, &c.

The conclusion of the matter, then, seems to show that the modern descendants of the ancient liberal or polite arts are what are now usually known as sciences rather than arts.

Now, as to what constitutes the precise difference between a science and an art is not easy to formulate in definite terms. Photography has been, and often is, termed an art-science, thereby implying that it partakes of the nature of both, without belonging exclusively to the one or the other.

This term has provided an ample target for the feeble shafts of the Piccadilly pundits. But, despite their superior information, it may well be questioned as to whether or not every art is at bottom the undeveloped embryonic form of a science.

It may, I trust, be taken for granted that science is knowledge, but it does not necessarily follow that all knowledge is science. A homely illustration may make this clear. The savage knows that he can "make fire" with flint and steel, or by friction of two bits of dry wood. He knows that certain plants, seeds, &c., will grow in certain places and not in others; that certain herbs, &c., may be used for foods, medicines, &c. But he does not bother his brain with theories of energy, friction, combustion, chemistry of soils, botany, physiology. Removed from his native surroundings, he is at a loss to know how to find substitutes. New experience has to be gathered. Induction and deduction are practically non-existent for him. Cultured man, however, has accumulated facts, experiments, observations. These he continues to arrange and rearrange with a view to grouping and connecting cause and effect, &c.

When this is done, his results have a permanent and systematic value. The under-current of knowledge connecting cause and effect is then dignified by the name of science. Scientific knowledge, then, may be broadly defined as that which may be formulated in logical sequence.

One curious and interesting point may here be noticed, viz., that, in the early days of the use of this term, it seems to have been especially, if not exclusively, applied to theology, whereas, in our own day, there are not a few who would deny this branch of knowledge having any claim to be called a science.

Turning to the *Encyclopædia Britannica*, we find an article (above the well-known signature "S. C."), from which may be gleaned Johnson's definition of art as "the power of doing something which is not taught by nature." This is found too narrow, and is amplified into the following: "Every regulated operation or dexterity by which organized beings pursue ends which they know beforehand, together with the rules and results of every such operation and dexterity."

The *Imperial Dictionary* (1851) divides arts into (1) the *useful*, or mechanic, . . . and (2) "the liberal, or polite; or, as they are now more frequently termed, the fine arts are generally understood to comprehend those productions of human genius and skill which are more or less addressed to the sentiment of taste or to the imagination—as painting, sculpture, architecture, engraving, drawing, and music."

The *Encyclopædia Americana* (1883) does not appear to contain any article under the heading Art. It is quite possible that the use of the term Liberal Arts at the present day in America is but another of the many cases where they, with a true conservative spirit, retain a meaning which we, ever fond of change, have sought to express by the newer term Fine Arts.

At any rate, it will be a matter of interest to many intending English exhibitors to know what are included or implied by the term Liberal Arts and Manufactures as used in the prospectus.*

The time seems not far distant when men will cease attempting to draw fine lines of distinction between science and art, and will recognise that no such sharp lines exist. On the contrary, the artist will cease to look upon the scientist as his natural enemy, and will hail him as useful helper and sometimes fruitful suggester.

In fact, there seem to be many points of analogy between the relationship of faith and reason on the one hand, and art and science on the other. In the former case, faith is not contrary to, but beyond, reason, and begins where reason ceases to carry us. In the latter, art is not contrary to science—*i.e.*, formal statement of truth—but, in turn, transcends and records flights of emotion and perception which, in our present state of knowledge, are only felt, but are not capable of experimental or logical analysis.

Science and reason appeal to the intellectual faculties, enabling us to say, "I know;" faith and art appeal to the emotional powers, and prompt us to say, "I feel."

F. C. Lambert.

JOTTINGS.

The development of partly printed proofs on gelatino-chloride paper, of which mention has occasionally been made of late, reminds me that many years ago—I think it was in 1855—the late M. Claudet published a formula for a simple process for exposing to daylight for a very short time, and then developing the weak image so produced. The process, if I remember aright, consisted of floating paper on a solution of mercuric chloride, and, when the paper was dry, sensitising on silver nitrate. The paper was exposed for two or three seconds in summer and up to about a minute in winter, the feeble image being fully brought out by means of an aqueous solution of iron proto-sulphate and glacial acetic acid. After washing, the developed print was fixed in hypo, a deep black image being obtained. I think at the time the paper was called the Instantaneous Positive Paper.

"Talbot Archer," the English correspondent of *Anthony's Bulletin* says "that the event of the month has been the opening of the first

* It may interest us to remember that, during the middle ages, the seven arts were commonly grouped into the *Trivium*, i.e., grammar, logic, rhetoric, and quadrivium, *i.e.*, arithmetic, geometry, astronomy, and music.

* The foregoing was written some two or three weeks before the writer heard Mr. H. P. Robinson's clever paper recently read at the Camera Club Conference. The reader may be referred to the concluding portion of Mr. Robinson's paper as touching upon the matter in question.

free public exhibition of survey photographs" at Birmingham. He informs his American readers that the "work has been taken up by some eight or ten other societies, but in a desultory and disconnected way, and, with the object of binding together for this grand work all the 300 photographic societies of the British Isles, Mr. W. Jerome Harrison read a paper on the subject in London before the Photographic Society of Great Britain on May 10th. Mr. Harrison urged that the 'parent society' (as the Photographic Society of Great Britain is still fondly called), should take upon itself the direction and organization of this grand work—a National Photographic Record and Survey. Such a task will be commenced, and must be completed;" but "Talbot Archer" fears "that the Photographic Society of Great Britain is in too 'fossilised' a state to furnish the men, the energy, and the funds which are needed to inaugurate this great movement." As "Talbot Archer" and Mr. W. Jerome Harrison are tolerably well known to be one and the same person, it would be interesting to be told whether the Photographic Society of Great Britain was discovered to be "in too fossilised a state to furnish the men, the energy, and the funds," before the reading of the paper or after? If the former, why was the paper wasted on such a Society? if the latter, what has the Society since done to merit such a criticism from one who was glad to avail himself of the opportunity to read a paper before its members so recently as May 10? If the Sociey has fossilised since May 10, the process must indeed have been a rapid one; and how is it that nobody but Mr. Harrison—or "Talbot Archer"—haa heard of that unfortunate change for the worse?

But, not content with smiting the Photographic Society of Great Britain because, I presume, that Society did not receive his photographic survey scheme with the enthusiasm which that "grand work" merits in the eyes of its originator, "Talbot Archer"—or Mr. W. Jerome Harrison—thus proceeds to employ *Anthony's Bulletin* as a vehicle for the following attack on the Photographic Convention of the United Kingdom: "The annual meeting of the Photographic Convention of the United Kingdom is this year to be held at Edinburgh, in the week commencing July 11. It is curious to notice the mistaken ideas which have prevailed on either side of the Atlantic with regard to the annual gathering or 'Convention' of photographers held in each country. *We* (I judge from the references in the English photographic press) regard your Convention as a wonderful success; and yet any one who reads between the lines of the American journals can see that it is a consistent failure, relieved by spasmodic efforts at success. But, if your Convention is a failure, what must be said of our dismal imitation? A meeting is announced at some interesting spot—Chester, Bath, &c. The expectations of the inhabitants are aroused, and they roll up in their tens on the opening day, headed by the Mayor, in his robe and chain of office. To them there appears some score, or perhaps even thirty, of photographers from London and other 'furrin parts,' consisting of the usual incapables who have hitherto 'bossed the show.' Excursions are made (always in heavy rain), and papers read before audiences of from fifty (on the opening night, when refreshments are provided free) to five at the finish." What a grotesque and prejudiced distortion of the facts!

This amiable critic of the Convention proceeds: 'This year there is some hope of better things, for the new heads of the Convention (Davison as President and Cembrano as Secretary) are a long way ahead in business powers and in popularity over their predecessors. Perhaps they may be able to persuade as many as fifty English photographers to follow them to Edinburgh, but I doubt it." Your American friends may like to know that the "usual incapables who have hitherto bossed the show" include, as Presidents, Mr. J. Traill Taylor, Mr. Andrew Pringle, Mr. Charles H. Bothamley, and Mr. William Bedford, with Mr. J. J. Briginshaw as Secretary, and a Council numbering such names as Cowan, Haddon, Lang, Mason, Sayce, Webster, Wellington, Bridge, H. M. Hastings, R. Keene, A. M. Levy, Henry Sturmey, John Stuart, of Glasgow, with many others who are recognised as men of sound practical ability, and who are identified with much that is best and most successful in modern English photography, as well as up to the year 1888, Mr. W. Jerome Harrison himself! The remainder of "Talbot Archer's" attack is based upon personal motives. I see that the forthcoming Convention will be attended by several distinguished American photographers, who, I have no doubt, will take back a different impression of its importance and proceedings than that which this biassed critic has attempted to create in advance.

I read that at a meeting of a Society—which, upon my word, sir, I hesitate to name for fear some unreasonable young member may take advantage of your benevolent pages to call me all sorts of names for daring to criticise his friends' remarks—and *apropos* of the subject of halation, "films were considered more rapid than plates." Upon what evidence? Surely not upon any theory that the nature of the support exercises some sensitising influence upon the emulsion? If that is meant, where are the proofs? COSMOS.

FUSED NITRATE OF SILVER.

NOTICING the correspondence that has ensued since my statement *re* fusing nitrate of silver, it occurred to me that it might perhaps be as well to add a few further remarks in the hope that they may be of assistance to those desirous of experimenting in this direction. Mr. Whitfield's suggestion that "fusing nitrate of silver renders it alkaline and forms a proportion of nitrite, thereby rendering it a more sensitive compound than before fusing," is partly correct, as the result depends upon certain conditions, and this increase of sensitiveness, as I have already pointed out, holds good both in collodion and gelatine, although it by no means follows that the action should be the same in both cases—in fact, many substances differ greatly in their action in the two mediums.

Thinking that probably the nitrite formed was the cause of the extra sensitiveness, I tried the addition of the nitrites of silver and soda to gelatine emulsion, but did not like the working of this, it being uncertain and prone to fog, owing perhaps to the instability of the nitrites. As regards the fusing, I found that to obtain the best results each different sample of nitrate required to be treated on its own merits, for, unless some samples were fused sufficiently, very little benefit was derived, whilst the same amount of fusing with other samples would develop decided fogging tendencies; and I think this admits of explanation from the fact that the first large crystals formed during the ordinary commercial process of manufacturing nitrate of silver are decidedly purer, or free from impurities, than the crystals obtained by evaporating the whole of the mother liquid; in the first case, simple dissolving in pure water and re-crystallisation would be all that was required for most practical purposes, but in the latter case it would certainly be an improvement to fuse.

To those who care to take the trouble I would suggest that, if they have an ordinary pure commercial sample, they fuse at a temperature of about 430° Fahrenheit; this will fuse the nitrate without forming any appreciable quantity of nitrite, and yet drive off most of the impurities. The lid should not be put upon the evaporating dish, and the melted mass should be gently stirred with a glass rod, as probably the action with nitrate is similar to that with metallic silver, which absorbs oxygen from the air whilst in a state of fusion and gives it off again when cold. Should the sample of nitrate operated on be an impure one, it may be necessary to apply greater heat. Perhaps as good a test as regards impurities in the ordinary way is the amount of scum that forms during the fusing; if this scum cannot be got rid of by continuing the fusing at the heat recommended, the temperature should be raised until it is dissipated, when nitrate will almost certainly be formed, and it is as well in this case to dissolve, when cold and set, in pure water, and then re-crystallise. It must not only be borne in mind that as the temperature is increased the nitrate is decomposed and nitrite formed, but also that, if the temperature be still further increased, the silver itself may ultimately be deposited in metallic form upon the bottom of the evaporating dish. J. BARKER.

OLD SILVER PRINTS.

I.

THE recent exhibition of old silver prints by the Photographic Society of Great Britain should point a moral with respect to the permanency of pictures made by this method. It is a mere truism to say that there must be a rule for the production of anything, if it can be repeated. The rule may be difficult to carry out or even, perhaps, to comprehend. Still, the rule exists, and it should not be ou[illegible]ing

the skill of modern photographers to understand and take advantage of. Where there are a great number of conditions, and the neglect of any one being sufficient to negative the advantages gained by scrupulous attention to all the rest, it only goes to prove how much more care is necessary to secure a properly prepared silver print than is usually accorded to it. From considerable experience, and in observing how many photographers go to work in this department of their profession, the fact that a very large proportion of silver prints are fugitive is no matter of surprise whatever—if they did not fade it would be the more astonishing; and that the reason they do so—the root of the matter, so to say—should have escaped the observation of so many is hard to understand. I attribute it chiefly to a blind following of a certain routine, and ignorance by the majority of *why* such a routine has been adopted, frequently added to an utter indifference to the work.

Formerly the printing department was deputed to boys and understrappers, who knew little, and cared less, about anything else than carrying out a certain sequence of processes. If the prints looked bright, clean, and of good colour when finished, that was the sum total of all they cared for, or all that was expected of them.

It was a long time before it dawned on the greater mass of photographers that printing operations required more intelligent looking after. Investigations were set on foot, many papers were written, discussions held, and the outcome of it was that, mainly, insufficient washing after fixing, and consequently the imperfect removal of the hyposulphite of soda from the prints was the principal, if not the only, cause of fading. Scores of washing machines were constructed, and the importance of the opinion was deemed so great that but few photographers neglected to avail themselves of the best means at their disposal for thoroughly eliminating the hypo from the paper. So far good; thorough washing is undoubtedly an excellent thing, but only one of the excellent things necessary to preserve the work, and those who look upon it as all in all lean as upon a broken reed. Prints that have stood the test of three or four decades without change are, in all probability, far from innocent of contamination with hyposulphite of soda. It would be instructive to get some of the best, and test them for the presence of this chemical. The probability is that it would be found in most, as, formerly, washing was a very perfunctory operation, and the supposed necessity for the thorough removal of the hypo was not thought of, and, if the prints were entirely deprived of it, it was more a matter of chance than deliberate intention. Notwithstanding this, many scores of pictures have remained bright and unaltered to the present time. The toning and fixing was one operation, but the bath was strong in hyposulphite, and the immersion long, too. The paper, also, was less highly glossed than we have it at the present time. The negatives were stronger, and the printing much longer about, with the result that the image was impressed right into the body of the paper, which had absorbed more of a very much stronger silver solution than is used at the present day. All these differences, no doubt, tended to make a more robust image than we are accustomed to see. At the same time, it would not wholly account for the freshness and good preservation of the half-tone that many of the photographs shown at the exhibition possessed; some other reason must be found for this, which I believe to be in the more effectual fixing they received.

The stronger silver bath and more heavily salted paper charged the print with a much greater amount of silver salts that required removing than now, in this respect the old prints were at a disadvantage; but the length of time and stronger bath used to fix and tone was equal to the work, and, although we might probably find hyposulphite of soda, I do not think we should find more than the faintest traces of silver, if any, in the whites of these pictures. There were also prints that evidently had been prepared from negatives of moderate density, that, as far as scale of tone goes, would compare favourably with our modern work. This narrowed the investigation to the fixing and washing, if we say nothing about the amount of albumen on the paper, which has undoubtedly some influence in the matter, but not sufficient to account for the rapid deterioration of the work of to-day unless supplemented by something very much more important, and this I quite believe to be inadequate fixing to which the majority of prints receive, and also, to go back to first causes, the poor, thin negatives used.

When the subject of permanency is discussed, the conditions for producing this very desirable quality are generally looked upon as uncertain—an opinion apparently justified by the results; however, it seems to me, if *known* conditions were *rigidly* adhered to, the uncertainty would vanish; but, unfortunately, they are not by a long way. At one time or another I have made many experiments in this matter, which have invariably pointed in one direction—that [illegible] and effective fixation, is an *absolute necessity*, and is not such [illegible] as it is generally considered, the fact of just putting the prints out of the wash water into the hypo bath, moving them about for a stated time, and followed by a good washing, being the whole, but most ineffective, procedure. Let us examine the method in detail. In the first place, the print as it comes from the toning abounds in silver salts more or less soluble, the greater part of which it is necessary to remove, seventy-five per cent. at any rate, the solubility being governed in part by the thickness and permeability of the vehicle containing them, usually albumen. Some, of course, are in the substance of the paper itself, but the aim has been to keep the image on the surface much as possible, and with many of the papers now in the market this aim has been successfully carried out. The photographer is very much in the dark as to the paper and its preparation, and has no means of gaining any information on the subject. It, no doubt, varies with every maker and albumeniser, but is sufficiently alike to answer its purpose with the same treatment. Hyposulphite of soda is the agent universally employed to fix the prints. It goes without saying, it should be a good sample.

EDWARD DUNMORE.

PICTORIAL SELECTION IN PHOTOGRAPHY.*

LIGHT AND SHADE.

We will next see what influence "light and shade," or "*chiaro-oscuro*," has upon pictorial effect. The words "*chiaro-oscuro*" are commonly translated "light and shade." Some writers prefer "clear obscure," or "light obscure." The term is used in reference to the lights and shadows of a picture, as also to its tones of colour.

In contemplating an extensive landscape it may have been noted that on the objects and forms nearest to the eye, the most brilliant lights and the deepest shadows are seen; and that, as the distance from the eye increases, these lights and shadows gradually diminish in intensity until they are ultimately lost, blending together in a kind of greyish-blue tint. Not only is it found that lights and shades lose their intensity in proportion to their nearness or remoteness from the spectator, but, as a necessary consequence, the contrasts also are less prominent, and the outlines less distinct, the more the distance is increased.

It may be as well here to state that there is a distinction between shade and shadows, the former being used in reference to those portions of opaque bodies which are removed from direct light, and the latter the deprivation of direct light suffered by another body, occasioned by the opacity of an object which intercepts it. That it is necessary to make this distinction is obvious, from the fact that in nature there is invariably found a difference in the intensity of these two kinds of shade, the shadow being almost always darker than the shade on the adjoining body by which the shadow is cast. This can be easily seen by taking a white object, say, a cube, and placing it on a sheet of white paper in a strong light, when it will be seen the portion of the cube in shade will be lighter than the shadow it casts. This difference is occasioned by reflected light; but it is unnecessary for me to do more than just refer to it, or detain you further on the matter.

It is the intention of a good picture to tell its story distinctly and intelligibly, avoiding all things which disturb the attention. This, without a good knowledge of *chiaro-oscuro*, cannot be done, for, unless the artist strictly adheres to the leading principles of this department of art, his labour will be thrown away. His first endeavour must be to obtain unity of light and shade by so massing his lights on the chief point of the picture that the eye may dwell on it with undisturbed satisfaction. To scatter over a picture at regular intervals a variety of objects having an equal degree of light is to produce a result more nearly approaching the nature of a chess-board, where the alternating spaces of black and white, so equal in size and power, allow the eye to wander over its surface finding not a single point of interest on which it can repose. The quantity of dark shade given in paintings is about one quarter; another quarter is allowed for light, and the remainder for middle tint. In many excellent pictures we see the greatest part occupied by middle tint, with very little positive light or dark, and in others we find a preponderance of light, with just a little "strengthening" or "darkening" of a part to create a focus for the whole. Generally in this latter composition small spots of colour, or strong contrasts, are introduced with telling effect, as is often to be noticed in some of Turner's charming works, in which a group of figures, a boat, or even a few broken posts, give extreme brilliancy to the picture.

As we are dealing with the camera now, it will be unnecessary for me to enter into the various methods adopted by artists in the treatment of

* Concluded from page 392.

chiaro-oscuro, because it is obvious the photographer's art is limited to the extent that he is only able to reproduce the subject as it appears before his lens, after a careful selection of his position, &c., and the due consideration of its most suitable lighting, whereas an artist has greater scope in introducing certain effects, which may enhance the beauty of the composition, although not actually present in the particular subject before him. This would be considered under the head of "invention," which need not trouble us here.

Supposing you have chosen your position, you will note how the objects in the foreground tell, the proportions of the strongest contrasts, the amount of brightest light and deepest shade in proportion to the remaining middle tint. See the shade and shadow is not in excess, so as to produce a dark and heavy result, and that the light does not preponderate, for an exactly opposite reason whereby a weak and insipid picture will be obtained. Do not hesitate to alter your position if these do not quite satisfy you, as no success is gained without labour, and a good negative is worth a little trouble. It will require some amount of practice to nicely determine the "values" of distant prospects, as in photography colour is reduced to black and white, with intermediate tones; but for near scenes, picturesque bits, old houses, &c., this difficulty is soon overcome when it is remembered what depth of tone certain colours produce.

Although unity of light must always be sought after, it must not be carried to too great an extreme, as repose will almost be lost by the eye being continually recalled to this isolated point (Fig. 9). In order that

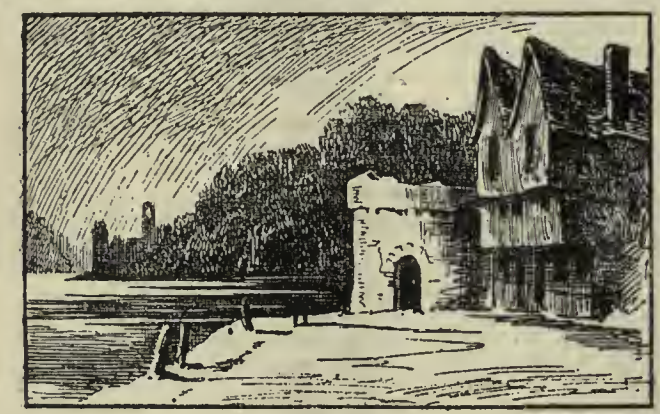

Fig. 9.

this singleness may be prevented, it is advisable that other groups of light should be admitted (Fig. 10).

These must be varied in their form, size, and degrees of power, and the breadth of the shadows so well preserved, that they may serve as places of repose to the eye, separating the groups from each other, that is, there should be *one* single portion having the most brilliant light—and consequently possessing the greatest contrast in the opposite depth of

Fig. 10.

shade—to which should be added other groups of light of a less degree of intensity, whereby both unity and repose will be secured.

The term "repose" is applied to those parts of a picture, either in deep shadow or middle tint, where lights and shades are so subdued that the eye can rest upon them without fatigue, after the excitation produced by the brilliancy and effects of the principal parts.

However objects may be scattered throughout the picture, they must be so grouped and collected together that, although each object has its own particular light and shade, the lights of all should generally mass together, as well as the shades, which will give a unity of effect always to be commended (Fig. 11). Cast shadows will be found of great assistance in

Fig. 11.

securing this quality of unity, inasmuch as, by passing from one object to another, they connect and hold them together (Fig. 12).

Seeing that shadows are more prolonged when the sun is low, it will be well to make exposures, when possible, either in the morning or afternoon rather than exactly at noon. As, in speaking of composition, it

Fig. 12.

was suggested that lines receding from the foreground were to be preferred, so, in the matter of shadows, parallel lines should be avoided.

Interest in Objects in Light.

It is important to observe that when any object is placed in light it is essential it should either possess some interest in itself or in its accessories in order that it may have that degree of interest which alone can allow the eye to rest upon it with satisfaction. Without such care it will appear bald and uncouth, and present an uninteresting and defective appearance. Thus, if you are about to select a rustic cottage with whitewashed walls, see that the portions in light have a few picturesque cracks between the stones, or across the plaster, are partly hidden by a creeper,

or an apple-tree close by. Perhaps a nail may be found on which to hang a bird-cage basket, some garden implements, a sieve, or article of wearing apparel. If a fisherman's abode, nets, crab-pots, oars and spars may be requisitioned, and failing all these, it will possibly afford a suitable position to place a figure, care being taken in selection of colour of dress in reference to contrast. If the ugliness cannot be overcome by any of these means it will be best to reject it altogether, or defer its portraiture until a more fitting time, when it may be seen in shade, and, in consequence, be less conspicuous.

To recapitulate, we have noticed the most brilliant lights and shades are in the foreground, gradually losing their intensity as distance increases, that there is a distinction between shade and shadow, the latter being the darker of the two, the intention of a good picture to tell its own story, which is impossible without good arrangement of light and shade, the great importance of unity in this matter to the getting rid of scattered light, various proportions of light and shade in compositions, the desirability of having more than a single spot of light and the proportionate intensity and variation in size of those added, the gathering together of scattered objects, the assistance of cast shadows, and the necessity of having interest in the portion in light.

To determine the most suitable manner in which we may introduce our figures, and to find the most appropriate position to place them in, must be our next endeavour.

Figures, &c.

There are but few scenes in nature, however beautiful they may be, upon which the eye can rest with continued pleasure unless they exhibit some signs of animated life; consequently, few landscapes are complete without the introduction of figures or animals, which shall enlist our sympathies on behalf of the scene presented to us, and, moreover, furnish us with a scale by which we may judge of the extent of the view and the size of every other object it may contain.

Who does not know how greatly a wild stretch of mountain and moor is enhanced by the presence of deer, shaggy cattle, or horned sheep? and, supposing it to represent a spot even too dreary to afford sustenance for these, how welcome is the dark form of a cormorant rising with heavy beat from a peat-stained tarn, whose waters, chafed by the flapping wings, break into silver ripples along its course to the opposite shore! Or, to take a pastoral scene, who will deny the increased interest manifested in the contemplation of an old timber waggon with its team of horses and rustic attendants, whose demeanour, perhaps, suggesting some slight incident, no matter how trivial in itself, not only gives to the whole an air of reality and truthfulness, but lends an additional charm to the prospect presented.

Views which consist in a large measure of water, be it river, lake, or sea, find their proper embellishments in ships' barges and fishing craft of all conditions of shape and size, and of every possible description.

It is very essential in choosing an object or figure to remember it should be "in keeping" with the rest of the picture. Thus, in a village scene consisting of thatched cottages, with trees, a tiny brook, and distant country beyond, it would be highly injudicious to introduce an individual whose chief attributes consist of a stove-pipe hat, with coat and trousers of the latest West-end cut and design, to say nothing of "spats" upon his feet, and a stick and glass complete, very proper, no doubt, to his mind, for Piccadilly, but utterly unfit for the purpose we require. Rather let us look about for one whose clothes bespeak honest labour, which have long since lost the creases they once possessed in the shopman's windows, having, in part, become moulded to the form which lives beneath them.

Another point I should like you to consider is the "pose" of your figures. It must be admitted that, in many cases, there is a lack of grace in country-side folk and a certain amount of crudeness, or angularity, call it what you like, about their natural attitudes. Perhaps no one better than a painter knows the great difficulty there is in overcoming this unfortunate effect, the most trying part of which is, that, the more you endeavour to get your models into a pleasing attitude, the more rigid and angular they become. They have the knowledge they are being "took," and, as they generally hold views diametrically opposed to those of the artist on such matters, a pleasing result is only obtained after much tribulation. This is, however, most to be remarked in persons of middle life and onwards, as children of both sexes and those in the hey-day of youth generally pose themselves in very pleasing attitudes, quite befitting their country life and occupation.

Whilst it should be your aim to place your figures in such a manner as shall present agreeable lines in your composition, be *very careful* you avoid the other extreme in giving them a species of classic pose more suggestive of Junos or Dianas than the simple folk of a country village, remembering you had better a thousand times have angular and even somewhat ugly forms in your pictures than that such a result should obtain.

These remarks apply to rustic scenes and general landscape views, and, inasmuch as a West-end fop would be "out of keeping" in proximity to thatched roofs and whitewashed walls, so would a ploughboy in a like degree be out of place in a London-drawing room, however much you might wish to emphasise contrast. Always see, then, that your figures are suited to the situation you intend them to occupy, and endeavour to place them in as natural and easy a posture as possible.

Now, as to where they should be introduced in your compositions. This will entirely depend on the subject you select, and what you determine shall be your strong point. If you decide that an object in the landscape shall first arrest attention, the figures will then have to hold a secondary position; but, if there is nothing of any particular interest in your view, let the figures be made of more importance. They will generally be found useful as a "balance" in the composition, or as a "contrast," the irregularity of their outlines being opposed to the lines and angles of buildings, as also their apparel, to the darker tones of vegetation, or *vice versâ*.

Another point you should consider is, whether you intend to make a "figure subject" or a "landscape with figures," as on this depends the size of the figures, or the space they should occupy. Avoid having them of such a size as would leave any doubt in the mind of the observer which was the more important part of the picture, the figures or the landscape. If the former, the prospect beyond should be broad and effective in its masses; if the latter, then the figures should be just sufficient to serve as a scale, and give additional interest to the whole.

In "grouping" care should be taken that no two groups are of the same size, nor placed in opposite positions. Always endeavour to have one group larger than any others, both as regards number and the space it occupies. Generally, groups should diminish in the space they occupy as they recede from the eye. If the light admits, try and connect them by means of the shadows they cast; sometimes a dog will be found very useful to this end. In placing your models avoid formality, aiming rather at irregularity in their outlines. You do not want a regiment of soldiers; hence never arrange them in line, have some portion of the group higher at one point or another, not forgetting that nets or farming implements carried on the shoulder will materially assist you in this direction. If you have a preponderance of vertical lines in your composition, let the figures pose in such a way as shall cut them obliquely; should horizontal lines be in excess, connect them with those of perpendicular tendency (Figs. 13 and 14).

Fig. 13.

The "relief" which figures afford in your pictures must receive some consideration; and, perhaps, in no instance will it be more necessary to remember what tones certain colours take when reduced to black and white. If this is overlooked, it will be found, after much care and trouble have been expended on their arrangement, you will get no effect, owing to the colours of the apparel worn by your figures being so near in tone to whatever may form their background.

If your background is light, you will have greater "breadth," if the tones of the dresses produce a light middle tint. If contrast is required, you will have recourse to pronounced tone; but, supposing you have a street view in some village, the brightest light being on the side of a house or wall, it is by no means necessary you should straightway select that spot as the most suitable to place your figures wearing the darkest clothes, unless you desire to rivet the attention of the observer on that particular point. It is impossible, in the infinite range of subjects which will commend themselves to your notice, to say where your figures should

be placed in every instance. If you have natural taste, positions will be suggested almost at a glance, and it will only remain for you to bear in mind some of the precepts which have been enumerated, in order to

Fig. 14.

determine which is the most suitable, in keeping with the laws of composition.

To those who do not possess this precious gift, but who are anxious to produce pictures having some claim to artistic merit, I can only advise they should endeavour to master these rules—a by no means insuperable task—at the same time taking note of good work executed by others, not only in photography, but in every branch of pictorial art, and, above all things, continually going to Nature, closely studying her under her many aspects, thereby acquiring a knowledge which can never fail to interest, and which will always elevate and refine.

Let me say, in conclusion, I hope these remarks on composition may assist you in your future efforts with the camera; and, although at first sight it may appear a difficult matter to overcome, it should be remembered, so vast is the importance of its principles to the artist, that any time spent upon their acquisition will be well bestowed. Of this, however, we may all rest assured, that no portion of sound knowledge is ever gained without some corresponding amount of exertion, and equally certain is it that "excellence is never granted to man but as a reward of labour."

The following works have been referred to in the foregoing remarks:—*Theory and Practice of Landscape Painting*, by George Barnard; *Theory of Painting*, by T. H. Fielding; *Model Drawing and Perspective*, by Williams. W. D. G.

NOTES FROM NEW SOUTH WALES.

Permanence in photographic prints is one of the subjects which seem to be open to perpetual discussion and controversy. In a recent issue of the Journal I notice that Mr. George Bankart, in a paper read before the Birmingham Photographic Society, places this point of permanence in the first position in urging the merits of the carbon process.

In this climate—the northern extremity of New South Wales—we have extremes of wet and dry weather, often with great heat in both cases, and my experience of carbon pictures is that, in hot, damp weather, they are often attacked by mildew, unless extraordinary precautions are taken; while in a dry heat they are apt to crack, especially where a deep shadow is pretty sharply contrasted with a high light. In looking at some very nicely executed copies of engravings, done on opal by the carbon process, I found them cracking all over and coming away in thin ribbons from the support. This occurred chiefly where there was little or no pigment; and it appeared to me that whatever substance—glycerine, sugar, or other material—had been used to give permanent flexibility and elasticity to the carbonaceous ink had either dried out or been insufficient to prevent it from contracting and tearing off in ribbons in the manner described. When mounted upon such a material as opal or metal, unless this property can be destroyed or neutralised in the gelatine ink, I am afraid carbon pictures upon non-porous, inflexible substances cannot be declared to be permanent. By the way, examples of most of the more commonly known processes may often enough be seen out here, but platinum prints are amongst the rare pictures.

Stereoscopic pictures were, some three or four years ago, to be seen in the windows of every photographic printseller and stationer, as well as in many of the opticians' and photographers' show-cases; in fact, there was quite a craze for them; stereoscopes (chiefly the "Holmes" pattern) and pictures were the fashion. This result appeared to me to have been brought about by the enterprise and push of some Yankee agents, who permeated the city, suburbs, and the country with their instruments and a stock of slides, which they were selling together at a fairly remunerative price, so many slides and a stereoscope for so much—about 25*s.* for, say, two dozen and the instrument. Some of the slides were very good, others inferior enough, and the demand gave rise to a supply of rubbish generally copied from others, often being made from two prints from the one view (monocular pictures). Some of the best I saw were Colonial views of yacht races, street scenes, seashore views, &c.; but, upon a subsequent visit to the city some twelve months or so later, all the stereoscopic pictures were gone from the windows, the fashion was past, and instead, optical lanterns greeted one's sight everywhere. Recently, the number of places for the sale of photographic requisites has largely increased, and the prices are comparatively moderate, running at twenty-five to fifty per cent. over English quotations, according to the article. The productions of all the leading makers can be had in Sydney and Melbourne, lenses at an advance of about twenty-five per cent., cameras 40*s.* to 50*s.* on advertised prices.

Photo-mechanical processes are beginning to be used during the last few years much more extensively than formerly—or, perhaps, I would be more correct in saying photo-zincography, if that is the proper term to apply to the pictures prepared for printing along with type. The *Illustrated Sydney News* (monthly) and *The Town and Country Journal* (weekly) are much indebted to photography for their pictures; and, in a lesser degree, the *Sydney Mail* and *Bulletin* (weeklies). The process seems to be similar to Ives' or Meisenbach's; but I am bound to say that there is much left to be desired in many of the reproductions. An ink-holding grain formed of a fine, uniform mesh does not readily lend itself to the exigencies of rapid and frequent printing with common ink on inferior paper; so that it is only the better journals which show satisfactory results.

A photolithographic printing company was started in Sydney, some few years ago, with a pretty large capital; but I am afraid it was in advance of our requirements, for although some very good lithographic work was turned out, the company did not seem to be a financial success. The process was a patent one, but what was its distinctive character I do not know. Very good photo-lithographic work is turned out at the Government printing-office here; but only recently one of the principal landscape photographers in the metropolis complained through the press of the fact that many pounds' worth of views, &c., were obtained by privileged persons at this institution free of charge to the recipients, but at the expense of the taxpayers generally.

Although there are a large number of professional and amateur photographers in the colonies, the societies are not at all numerous nor "much in evidence." There appears to be one in the capital of this colony, only two in Melbourne (Victoria), two in Brisbane (Queensland), and one in each of the other colonies except New Zealand, where they are more numerous. It should be an interesting, instructive, and profitable speculation, if carried through with judgment and energy, to have an exhibition of photographs in each of the colonial capitals, at which the various prize pictures shown in Great Britain would be exhibited, along with others of great merit, and some of our best colonial pictures. I think a great deal could be learnt by both professionals and amateurs by the opportunity for inspection and comparison. We should, at any rate, be able to judge of the position held by the colonies in the art-science as compared with the mother-country. Many of the pictures should find purchasers if for sale at reasonable prices.

In the matter of portraiture, I think our best artists can hold their own with most of those which I have had an opportunity of seeing from the old country, but there has been a very extensive adoption of the "enamel" finish to portraits, especially in the country towns.

Prices vary, too, almost as much here as they seem to do with you. The "Cabinet" is the size most largely patronised, and they can be got from 10*s.* or 12*s.* per dozen (or, I think, even less) up to 2*l.* 10*s.*, the mean being about 15*s.* to 1*l.* 5*s.*, for which price very good work is given.

Occasionally a fashionable photographer in the city gets a sitting from an actress, or some other celebrity, who is temporarily "the rage," and the pictures are sold by thousands. I understand this occurred in the case of Mrs. Brown Potter, Madame Bernhardt, and one or two others. I was not fortunate enough to see the originals of two or three of these "Beauties"—a matter of regret to me, as the photographs have left me wondering what all the world went crazed over. If I accept the photographs as trustworthy portraits, I should say that America and this colony have given the two most beautiful women to the stage, and they have both abandoned it.

I am sorry to say that very few portraits now can be relied upon to any great degree. The "Retoucher" frequently remodels the picture so extensively that one often does not recognise his friends.

A. J. Simpson.

Our Editorial Table.

Adams & Co.'s Photographic Annual, 1892–3.

Prefixed by a number of practical articles on topics of photographic interest by Captain Abney, Messrs. H. P. Robinson, Andrew Pringle, W. Willis, and other writers, this well-printed and lavishly illustrated *Annual* supplies an excellent guide to the innumerable productions of Messrs. Adams. It is most complete and comprehensive, and is in its way a clear indication of the expansion of modern photography.

Eastman's Gelatino-chloride Printing Paper.

We are very glad to see that the Eastman Company has introduced a new printing-out paper, for we know that their establishment at Harrow is so perfect and well equipped as to lead us to anticipate no failure in keeping up the output of anything they now undertake.

The gelatino-chloride paper is issued in two forms, one being pure white, and the other with a delicate warm tint, this latter having a *soupçon* of roseine, although not pronounced. In surface appearance the paper is almost identical with albumenised paper, and we note its entire freedom from specks or defects. When placed under a negative in the frame, it prints with great rapidity, exceeding in this respect all the samples of ready-sensitised albumen paper we have of late had access to. It takes a good tone in the printing, and a special feature is, that it does not need to be much over-printed. Although, after printing, the subsequent operations of toning and fixing may be carried out just as usual, yet is a special formula for toning and fixing at one operation recommended. It is as follows:—

Combined Toning and Fixing Bath.

No. 1.—*Alum and Hypo Solution.*

Hyposulphite of Soda	8 ounces.
Alum	6 „
Water	64 „

When dissolved, add to above three ounces carbonate of soda, dissolved in eight ounces water. (This must be added very carefully on account of the effervescence which takes place.) Allow to stand twenty-four hours, then decant the clear liquid.

No. 2.—*Gold Solution.*

Chloride of Gold	15 grains.
Acetate of Lead (Sugar of Lead)	64 „
Water	8 ounces.

To make the toning bath:—

Take of No. 1 Solution	8 ounces.
Take of No. 2 Solution	1 ounce.

After printing, immerse *without previous washing* in the above toning bath until the desired tone is obtained.

The above solutions will keep any length of time.

When toned, transfer the prints to the washing tray, giving at least one hour and a half's thorough washing in several changes of water.

Should any other formula be used for toning, the prints, when toned, must be washed in two or three changes of water, and then fixed in a bath of hyposulphite of soda of the following strength:—

Hyposulphite of Soda	3 ounces.
Water	1 pint.

Care must be taken to keep the prints in continual motion, in all solutions.

From the trials we have made of this paper, we are greatly pleased with it, and must congratulate those concerned upon its introduction.

We have also received the catalogue of the Blackfriars Photographic Company, of Surrey-row, S.E. This is a very bulky volume, in which illustrated particulars of the principal photographic materials in general request are given, including the firm's own specialities.

Meetings of Societies.

MEETINGS OF SOCIETIES FOR NEXT WEEK.

Date of Meeting.	Name of Society.	Place of Meeting.
June 27	Dundee Amateur	Asso. Studio, Nethergate, Dundee.
„ 27	Gloucestershire	
„ 27	North Middlesex	Jubilee Hall, Hornsey-road.
„ 27	Rossendale	Townsend-chambers, Rawtenstall.
„ 28	Great Britain (Technical)	50, Great Russell-st., Bloomsbury.
„ 28	Lancaster	Storey Institute, Lancaster.
„ 28	Leith Amateur	
„ 28	Warrington	Museum, Bold-street, Warrington.
„ 29	Bath	Roy. Lit. & Sc. Inst., Terrace-walks.
„ 29	Burnley	Bank Chambers, Hargreaves-street.
„ 29	Photographic Club	Anderton's Hotel, Fleet-street, E.C.
„ 30	Halifax Photo. Club	Mechanics' Hall, Halifax.
„ 30	Hull	Royal Institution, Hull.

„ 1	Richmond	Greyhound Hotel, Richmond.

LONDON AND PROVINCIAL PHOTOGRAPHIC ASSOCIATION.

June 16.—Mr. P. Everett in the chair.

Messrs. R. P. Drage and J. Weir Brown were appointed delegates to the Convention.

Some Prime Factors in Exposing.

Mr. E. Howard Farmer delivered a discourse on this subject, and said that, if it was not new or interesting, it was important educationally. In photography nowadays, as in other subjects, people were not satisfied to work by rule of thumb. For the student a knowledge of principles was of great value. A great deal of attention had been given to the production of tables and instruments, which, by mechanical means, gave the time of exposure. Such aids as the Watkins exposure meter and Messrs. Hurter & Driffield's actinograph were of great value as labour-saving implements or tools, enabling a photographer to arrive at his correct exposure without the exercise of brain energy, and anything which saved that was of value. His purpose that night was to try and show the extent to which the ground covered by these tables had already been gone over. There were four methods of ascertaining the exposure:—(1) Where the exposure was guessed; (2) where it was judged of solely by the illumination of the ground glass, a method largely used at the present time; (3) referring the subject to some other subject of the same nature taken under similar conditions; and (4) that in which the worker, so far as he knew, took into consideration every factor which regulates the exposure and allows for each of them in the particular subject he was going to expose for. The first method was like betting, it was all the odds on the exposure being wrong. As to the second, many operators simply judged by experience, and, where the operator had sufficient experience, the accuracy was surprising, but when they came to the young beginner that method was practically useless; besides, it had sources of error which were unrecognised. For instance, hardly any two pieces of ground glass gave the same brilliancy of image, and that made a difference. Again, different atmospheric conditions made a considerable difference in the brilliancy of the image, and so did moisture and grease on the ground glass. The third plan was a most excellent one, where the operator had the previous experience, and where notes of the exposures on similar subjects were kept for reference. The fourth method consisted practically in making a sort of equation in which A, B, C, &c., were the known factors, varying under different conditions, and the exposure required equalled x; and some such plan as this was necessary until sufficient experience had been obtained by the worker. All the actinometer tables and photometers were based on this method, and he proposed to show how far that method went. (*a*) An operator working in a studio rarely used his lens quicker than *f*-4 or slower than *f*-32; for outdoor work, *f*-8 or *f*-64; and for interiors *f*-16 or *f*-120; and this gave a variation for ordinary work of 1 to 60. (*b*) The sensitiveness of the film—taking Wratten's instantaneous plates, which were about 18° on Warnerke's sensitometer, as a guide—varied about 1 : 10. (*c*) Power of the light. With the altitude of the sun down to one or two degrees, the variation would be about 1 : 16; at 60° or 70°, 1 : 2; in dull weather, about 1 : 4; the extreme range thus being about 1 : 64. (*d*) The variation in the amount of light cut off by trees, in interiors, &c., was unlimited; in connexion with which he mentioned having taken the interior of a city church which required an exposure of a fortnight. He had thus assumed certain conditions, namely, the working aperture of the lens as *f*-8, the sensitiveness of the plate to be that of Wratten's instantaneous (15° Warnerke), the sun at an altitude of 30° to 40°, with a blue sky and a fairly constant light. As to (*c*), the subject, it was not nearly recognised to what an enormous degree this regulated the exposure; while in regard to distance a great difference of opinion prevailed. Supposing, then, they were standing on a hillside looking at a town in a valley three or four miles distant, with the sun shining, and, say, one or two friends in the foreground, the proper exposure (with the foregoing conditions) would be one-thirtieth of a second. Going to within 100 feet of some trees, the exposure would be increased to one-eighth of a second; quite close under the trees, it would be one second; and, very near indeed, it would be four seconds. The difference in the exposures was due to their having to expose for the shadows. The first subject was actually in sunlight, but at a distance of 100 feet there were portions not in sunlight, necessitating a longer exposure, while up to the trees there was no sun. This method was in employment at the Polytechnic. The students were sent out to take a certain subject, and give a certain ex-

posure; and, if this was found incorrect, they had to take the picture again and again. Thus they had got together a mass of evidence of the greatest value from an experimental point of view. The same remarks as to distance and the effects of lights and shade held good with regard to studio work and interiors. An easy method of illustrating the effect of distance or exposure was obtained in the case of a hedge. Being close to it, one could see into dark portions of it; but, getting further away, those dark places were not seen. The colour of objects ranging from snow to hillside grass and a dark Devonshire cliff; of white statues, groups, bronze figures; of a grey-haired man, an ordinary individual, and a Hindoo, gave considerable variations, the range being from 1 : 60.

Having briefly considered as factors the object aimed at and the size of the plate in proportion to the original, Mr. Farmer said he thought the exposure meters did not sufficiently take into consideration some of the most important factors which regulated exposure. In Messrs. Hurter & Driffield's actinograph the light, the aperture, and the sensitiveness were allowed for, but the other factors were not. But how far was it possible to give particulars for those other factors? He indicated a table of distances as the basis of exposure, such distances being taken from the camera to the nearest important shadow. Comparing the light in different parts of the world with that of England, he said he found the light of the Canadian prairies the most actinic, being twice as quick as that in England, which he accounted for by the country being very flat and the ground very light. A large proportion of the light was reflected from the ground. Diffused light was no quicker than in England. In conclusion, Mr. Farmer passed round a number of pictures in illustration of the chief points of his discourse.

Mr. A. Cowan thought that Mr. Farmer had made out a good plea for one addition to the actinograph of Messrs. Hurter & Driffield. The table of factors was not sufficiently large, although, so far as the table went, it was very correct. Mr. Farmer's four first factors must be correct.

Mr. J. R. Gotz, in reference to the lens at *f*-8 as a factor, said that the exposure would be longer for a wide-angle lens of the same focus than for a narrow angle.

Mr. A. L. Henderson considered the fortnight's exposure, to which Mr. Farmer had referred, as "incomprehensible."

Mr. J. S. Teape had used the actinograph several times, and found it very accurate as a guide, but said that, in photographing a village scene with the trees in shadow, and the sun striking over the tops of them, the actinograph indicated twenty-four seconds. He (Mr. Teape) gave a minute, and the plate was only just about correctly exposed. He thought note should be made of such cases for guidance.

Mr. J. Weir Brown, in regard to the colour of light at different times of the day, said that the relative rapidity of some plates he had recently been trying increased from 4 : 6 in the afternoon, to 1 : 6 in the evening. The light must have been of a different quality at seven o'clock than at four o'clock.

Mr. W. E. Debenham said it was desirable not to take the last numbers visible in the Warnerke sensitometer, but to take that part of the plate where the straight line in Messrs. Hurter & Driffield's curve came in. He mentioned this ten years ago to Mr. Warnerke, who agreed with him. He (Mr. Debenham) and Mr. Burton both made some experiments with regard to auxiliary exposure as affecting the sensitometer value of plates, and they found that a certain plate with auxiliary exposure could be made to register a speed sixteen times greater than without. Of course this could not be taken as a guide for exposure.

Mr. Farmer having replied to the discussion, a vote of thanks was passed to him, and the meeting terminated.

Holborn Camera Club.—June 17, Mr. J. H. Avery in the chair.—Mr. A. J. Golding gave a demonstration on *Carbon Printing*, using the tissue as sent out by the Autotype Company. This printing process was, in Mr. Golding's opinion, one of the most charming. Mr. Golding gave a number of hints during the demonstration, and developed a few prints to illustrate his remarks. On Saturday, June 18, outing to Pinner and Ruislip, where a very charming day was spent in spoiling plates.

People's Palace Photographic Club.—June 17.—"Outing" work was shown by Messrs. Cable, Walker, and S. J. Beckett. Mr. George Patten handed round some whole-plate prints from negatives taken in the Lake District; he also showed some marine views, printed on Whatman's drawing-paper, which he had himself prepared. These were much admired. Mr. Cable asked why his prints sometimes printed a blue colour and sometimes of a red-brown tint? In reply: It depended upon the amount of moisture contained in the paper. If bone-dry, it printed blue. It was thought a certain amount of atmospheric moisture was necessary for getting the best results. Mr. G. Kendall, referring to his previous experience of marbling-like stains on his plates after developing, said he had overcome that by putting the plate in water before flowing on the developer. He, however, was still unable to account for the cause of the stains.

Harlesden and Willesden Photographic Society.—The members of this Society made an excursion on Saturday last to Cassiobury Park, Watford. The occasion was a most enjoyable one, and, notwithstanding the unsettled state of the weather, some charming bits were obtained. The next meeting of the Society will take place on Tuesday, the 28th inst., at "Sunnyside," 50, Craven-park, Willesden. Intending members are invited to communicate with the Hon. Secretary (Mr. Woodbury), 23, Fairlight-avenue, Harlesden, N.W.

Richmond Camera Club.—Since the beginning of the summer session weekly meetings, chiefly of an informal character, have been held and, considering outdoor attractions, well attended. On the 10th inst. Mr. Ardaseer gave a demonstration of the process of toning with salts of platinum. The process was clearly and concisely explained, and a number of prints were toned by way of example. Club excursions have been made to Perivale, to Hayes and Keston, and to Penshurst.

Manchester Photographic Society.—June 16, the President (Mr. Abel Heywood) in the chair.—After the formal business a number of the recent developments of what may be termed modern photography were brought under review; the first was the use of films as a support for the negative. Mr. C. H. Coote gave his experience of the films used in the ordinary double backs. As regards the working he found no difficulty, and his results were in every way equal to glass negatives, the saving in weight could be judged from the fact that three dozen films did not exceed in weight three glass plates. Isochromatic photography was treated in short communications from Mr. Whitefield and Mr. Brier. Both gentlemen arrived at similar conclusions with regard to the use of the yellow screens, namely, that with ordinary plates very little was to be gained, but with isochromatic plates the results with screen were superior to those taken without. From experiments Mr. Whitefield had made, a dark screen did not over-correct the blues as compared with the yellow. Mr. Brier considered that for landscapes the isochromatic plate and screen rendered a better gradation of tone, especially in the sky, though it showed the exposure in a good light about three times. During the evening Mr. Brier explained the working of the new cold-bath platinotype paper, and demonstrated the simplicity of the process by developing about a dozen prints. One great merit of the paper was that, the development being gradual, the result was better under control. The finished prints have a very good black tone, and the detail is remarkably well rendered. Mr. Brier also contributed the following notes on the working of the new Anastigmatic Lens by Zeiss, of Jena:—"After most careful and thorough trial of the lens last winter, I was so convinced of its great superiority over all other forms of lens, that I purchased one of 5¾ inches focus for a new quarter-plate travelling outfit I was making. I have since used this lens for about 200 exposures, the results of which quite satisfy me. To put the virtues of the lens into as few words as possible, it possesses the most perfect defining powers in the centre of the field of view at full aperture of any lens I know. Secondly, being a lens of great covering power (or wide angle), and giving excellent marginal definition, with a comparatively large aperture, on a large surface, relative to the focus of the lens, it can be most successfully used for short exposures on subjects requiring such powers. I draw your attention to a few examples, in which, though only four inches by three, the lens has practically been covering a plate of twice those dimensions, and has defined well close to the margin with the large aperture of 12·5. Then, there is the freedom from astigmation, as it is called. Well, this astigmation is nothing more or less than a confusion of the pencils of light, generally getting worse as the margin of the field of view is approached, or it may be quite central on points or objects which are out of focus; but the best (or worst) way of arriving at this beautiful result (with any lens) is to focus sharp on a very near subject, leaving all distant ones to take care of themselves. Well, this Zeiss lens just gives as little confusion as possible, if properly used. I show you comparative results between it and a recently produced lens of similar focus by one of our most noted opticians. The lens is a most excellent one for enlarging with, as at full aperture it will give better definition than otherwise good lenses will when stopped down to a fourth of its rapidity; but care should be taken to keep the light out of the lens, except when necessary for focussing and exposing. I do not think this lens desirable for hand cameras, its powers of covering are not required, and it is better for being accurately focussed."

Rotherham Photographic Society.—June 14, Mr. E. I. Hubbard, M.S.A., in the chair.—Two new members were elected. The principal business was the consideration of a paper on *Stereoscopic Photography*, read by Mr. Leadbeater. He argued that stereoscopic pictures possessed a charm not to be obtained by any other means of picture-making. He had recently renewed his acquaintance with this branch, and had obtained most satisfactory results, many of which he exhibited. On Friday, the 17th, the members had an enjoyable excursion to Haddon Hall, Derbyshire. The first "outing" of the season was to Comsborough and Sprotborough on Saturday, May 28. Beautifully fine weather prevailed on both occasions.

Correspondence.

☞ *Correspondents should never write on both sides of the paper.*

ORTHOCHROMATIC PHOTOGRAPHY.

To the Editor.

Sir,—We notice in the paper read by Dr. Acworth before the Photographic Society of Great Britain, of which a report appears in your last issue, many inaccuracies, some of which we must beg to correct.

Dr. Acworth mentions the name of Mr. Clayton as one of the workers in connexion with isochromatic photography. Probably no one would be more astonished at the honour thus conferred on him than the gentleman in question, who in reality had nothing to do with working out the process, his name occurring on the English specification merely because he was at that time in business partnership with the real inventor, Mr. Attout Tailfer, to whom, as stated in your columns by Colonel Waterhouse long ago, "alone is due the credit of the successful application of the colour-sensitising properties of eosine to the gelatino-bromide process."

In Dr. Acworth's incomplete description of the Tailfer process, he speaks of it as an optically sensitising process, and of the plates prepared by it as containing "an enormous quantity of dye." Any one who will read Tailfer's specification will see that this is altogether erroneous, and that the eosine, or erythrosine, is not used as a "dye," but as a chemical sensitiser, only so much of it remaining in the film as is combined with the silver bromide. The plates are not dyed at all, as Dr. Acworth supposes, and, in fact, differ very little in colour from ordinary plates, as can be seen by examining any of our isochromatic plates. The

system of "optically sensitising" by means of dyes is well known as Dr. Vogel's, and should not be confused with the Tailfer process of chemical sensitising.

With regard to Dr. Vogel's English patent, it is perhaps not generally known that this patent was never issued according to the original specification, the sealing of the British patent being successfully opposed by ourselves on the ground that it was, to all intents and purposes, a copy and infringement of Tailfer's invention; consequently, by order of the Comptroller, Dr. Vogel's principal claims were struck out, and a disclaimer inserted, the legal effect being that the process, if used at all in this country, could only be so used by licence under the Tailfer's patent; doubtless this is why the Vogel patent was allowed to lapse.

The process, however, was no improvement, and never had any commercial value, for the reason admitted by Dr. Acworth, that plates prepared by it with free silver will not keep, neither are they any more colour-sensitive than properly prepared isochromatic plates, which have the additional advantage that they are equally as permanent as ordinary plates.

Finally, in quoting M. Leon Vidal, and speaking of the isochromatic plates manufactured by the firm of Lumière, of Lyons, Dr. Acworth omits one important fact, which is, that this firm holds a licence from Attout Tailfer under his French patent.—We are, yours, &c.,

Hackney, June 21, 1892. B. J. Edwards & Co.

CORRECT EXPOSURE.

To the Editor.

Sir,—I cannot help wondering whether Mr. Michael has made any definite trials with a view of finding out the truth in this matter. If he had, I am sure that he would find that his theory of a wide-angle lens requiring less exposure than a narrow-angle one when used with the same ratio of stop under identical circumstances to be quite incorrect.

I have just made a definite experiment in the matter. One half of a 7½ × 5 plate was exposed with a seven and a half inch single Wray lens at *f*-32 for three seconds, the other half being marked. The unexposed half was then exposed on the same subject from the same standpoint with a twelve-inch single Wray lens at *f*-32 for three seconds, the two exposures being within five minutes of each other, and the light (unclouded sunshine) being unchanged. The two exposures received, of course, the same development, and I enclose the negative.

Would you, sir, kindly say whether there is any sign of inequality of exposure, which would be the case if Mr. Michael's theory were correct? The plate is an old make, and one end of the film thin. I must be excused from entering into an explanation of the fact *why* a large amount of subject reflects no more light to a square inch of the sensitive plate than a small amount does. It is a question which the opticians have not touched upon.—I am, yours, &c., Alfred Watkins.

Hereford, June 18.

[We have examined the plate sent, and cannot detect any sign of inequality in the exposure of the two images.—Ed.]

To the Editor.

Sir,—Mr. Michael does not appear to have noticed that in keeping the same ratio of aperture to focus (May 20, page 335) he has changed the area of the stop, and made exactly the allowance for which he contends. In the second case, four times the area of object, giving four times the light, is made to cover the same area of plate as in the first instance, but the stop has been reduced to a quarter of the area, and allows exactly the same amount of light to pass as before.

The exposure required is therefore equal in both cases, or, as he expresses it, "the lens works at the same intensity."—I am, yours, &c.,

Redlands, Red Hill, June 20, 1892. John Sterry.

"JUNIOR" AND "COSMOS."

To the Editor.

Sir,—"Cosmos" challenges me to point to a supposition, implied or expressed, that the London and Provincial Photographic Association was aimed at in his remarks. I refer him to the sixth paragraph of his "Jottings" in The British Journal of Photography, June 3. In the fourth paragraph he mentions the London and Provincial, and in the sixth he proceeds to elaborate his attack by gibes at the clever persons who regularly snubbed the younger and less-informed members in his days. Further on, he states that the wise members of the Society to which Mr. Haddon belongs were unable to answer a certain question, and referred it to the examiner. The whole paragraph points to the London and Provincial; but, as the attack was by *innuendo*, I denied its truth in the only manner possible, viz., "*if* applied to our Society." Were I so disposed, I might take advantage of your contributor's defective grammar in the first phrase of paragraph six, where he writes Society in the possessive singular instead of the plural.

With blushing reluctance "Cosmos" will hardly admit that "not long ago" is inconsistent with "several years ago." If "several years" means "not long," then "Cosmos" should change his *nom-de-plume* and subscribe himself Methuselah, for with him years must be as days. But—most extraordinary of coincidences!—you may remember, Mr. Editor, that at the meeting of the London and Provincial, on May 5, one of the members mentioned he had been informed by a chemist's assistant that recrystallised nitrate of silver sold by his firm was merely the large crystals picked from the ordinary stock. This is the very thing "Cosmos," eight days later, stated he had heard not long ago at a photographic society, and, to his own discredit, bore witness to the fact of such dishonest practice. I do not say "Cosmos" heard this remark at the London and Provincial. He lives 200 miles away. Besides, he is very old, and would not visit London, because he would have to travel by that abominable modern invention, a railway.—I am, yours, &c.,

June 18, 1892. Junior.

To the Editor.

Sir,—In common with many other members of the London and Provincial Photographic Association, I was somewhat at a loss to understand the onslaught on friend Haddon by "Cosmos" in your impression of the 3rd inst. I even had unkind thoughts of your correspondent and dim visions of "writing to the papers" on the subject. His letter this week, however, has disarmed me, and I now bear him no ill-will. It must be very difficult to successfully ridicule the proceedings of photographic societies when you have only the reports in the journals to guide you, and when a correspondent lives nearly two hundred miles from London, and has not attended a meeting of a photographic society there since "Junior" was in long clothes, the difficulty must be still greater.

Since "Junior" was in long clothes! Dear me! why at that time there were only two or, at most, three photographic societies in London; now we have them in almost every parish. So the young members were "snubbed" in those days, were they? How things change! Now it is the folks who *don't* go to the meetings who try to do the snubbing.

"Cosmos," I notice, commends the wisdom of "Junior" in not signing his name. It is as well to write under a *nom-de-plume* sometimes. Had "Cosmos" set a better example, perhaps "Junior" might have followed. I say *might*; but he might not then have considered it worth while to reply, or might not have cared to risk having half a page of expletives flung at him—who knows? Oh, I *am* glad I did not reply to his letter.—Yours, &c., Another Junior.

[Come, come, good friends; we put it to you whether enough and to spare has not been said on both sides of a matter which seems to have given rise to a good deal of misunderstanding all round.—Ed.]

THE ECLIPSE HAND CAMERA.

To the Editor.

Sir,—My attention having been drawn to Mr. Kinnear's letter of the 17th, I feel compelled to reply to that portion of it which is likely to mislead.

Referring to my specification of a patent, published in the Journal of the 10th for improvements in hand cameras, he says:—"This plan I had applied to my camera in March last, principally, no doubt, as a means of focussing, the want of which, except by sliding the lens in a tube, which was never satisfactory, being a serious defect in the Eclipse form of camera."

From this I assume that Mr. Kinnear does not know of the existence of my focussing flange, which enables the operator to focus with absolute precision from infinity to within five feet without in any way increasing the bulk of the camera or lens.

With regard to Mr. Kinnear's suggestion or claim of priority of invention, I am unable to comment on the addition he has to his camera, the object of which he appears somewhat in doubt; but does he suppose that a patent filed in June required no time to bring it into existence? As a matter of fact my swing-back device was made and tried as far back as January last, but was not secured owing to difficulties that had to be overcome with the sliding wings, every part being so slight.

With my design the swing obtained is so great that there is no need for raising the front, and I further obtain a greater local range than has, owing to the peculiar construction of the spring fittings, a greater focal range than has hitherto been possible on a camera of such small dimensions.

Surrounded as I am by cameras with swing backs of ancient and modern construction, it is scarcely probable that I should patent a swing arrangement with no novelty in it, as Mr. Kinnear assumes; but my object is more than attained if so good an authority as he is convinced, as he says that these improvements "will undoubtedly make this form of camera more generally useful."—I am, yours, &c., F. Shaw.

87 & 88, *Newman-street, London, W., June* 22, 1892.

Exchange Column.

Answers to Correspondents.

All matters for the text portion of this JOURNAL, *including queries for "Answers" and "Exchanges," must be addressed to* "THE EDITOR," *2, York-street, Covent Garden, London. Inattention to this ensures delay. No notice taken of communications unless name and address of writer are given.*

*** *Communications relating to Advertisements and general business affairs must be addressed to* "HENRY GREENWOOD & Co.," *2, York-street, Covent Garden, London.*

PHOTOGRAPHS REGISTERED:

Samuel Powell, Rushden, Higham Ferrers.—*Baptist Missionaries' Group. Baptist Ministers' Group.*

George Emberson, Chertsey, Surrey.—*Portrait of John Dalma.*

A SUBSCRIBER.—Consult the information on toning in the ALMANAC.

JOSKIN.—1. We believe Messrs. Marion and other firms supply such rims. 2. "Name It" will probably suit your purpose.

L. S. D.—Gum arabic is not soluble in methylated spirit, therefore there need be little wonder that you failed to make a solution.

PICKWICK.—The paper has clearly been exposed to light before it was placed in the enlarging camera. Hence the cause of the fog.

SCOTIA.—We have not tried such a method, but see no reason why it should not answer. Better give the plan a trial, and thus prove, in practice, if it answers your requirements.

W. A. M.—The "phenomenon" you describe was brought about by your putting the plate wrong side foremost in the slide, so that the glass side was next the lens instead of the film.

ROBERT WILSON.—The quantity of pyro does not strike us as being excessive. The solution can be used for several prints. Take the solids as grains instead of parts, and the water as 2 oz. I dr.

S. H. P.—We see no objection to your making transparencies for enlarging from on the specially prepared lantern plates, instead of in carbon. If the transparencies are equally good, it matters not by what process they are made.

H. SUSMANN.—We did not take note of the date of the *Standard* in which Dr. Vogel's communication appeared. That gentleman's views of Mr. Ives' method are, we should think, sufficiently clear from his letters in our own columns.

LIVERPOOL.—The primuline process is patented, but you may obtain a licence from the patentees. If you only want to work the process as an amateur, we believe a licence is not required, provided you purchase the material of the patentees or their agents.

W. CHARLES.—At this season of the year the strength of the solution for sensitising carbon tissue should not exceed three and a half or four per cent. In winter a stronger bath is advantageous, say one ounce of the bichromate of potash to a pint of water—or five per cent.

E. B. J.—Dextrine, as we have said several times before, is not a suitable mountant for silver prints. It is a convenient material to use, it is true; but, unfortunately, it is almost invariably acid. Consequently, it should be avoided for photographic purposes, or at least so far as silver prints are concerned.

E. W. A. S.—There may be several reasons why the prints do not tone. The paper may be at fault, or the bath upon which you sensitised it may be out of order. The same remark applies to the toning bath. Make an entire change of the materials used. This will prove whether the chemicals, or the manipulations, are at fault.

W. B. says: "I have an old lens, rather large, and the following is the maker's name: Jamin, ingénieur opticien, breveté s.g.d.g., 14, rue Chapon, Paris. Could you tell me what kind of lens it may be, or if there is still a firm of that name in Paris?—It is evidently an old portrait lens. Jamin has long been succeeded by the firm of Darlot.

R. BOTHWELL complains of the returns made by a refiner for some residues sent for reduction. As our correspondent appears to have no idea as to the quantity of silver contained in the residue beyond that they weighed so much, with such data it is quite impossible to form any judgment as to whether the return was fair or not.

LUX.—1. If the negative has been intensified with uranium dissolve out the latter in a solution of sodium carbonate, and, after well washing the negative, bleach with mercury and redevelope with ferrous oxalate. If sufficient density is not then obtained, repeat the operation. 2. Probably a solution of citric acid will remove the stain.

C. WILLIAMSON asks if there is any objection to smoking in the dark room while developing—that is, will the fumes act injuriously on the plate?—So far as we know, tobacco smoke has no effect whatever. As a matter of fact, it may be safely affirmed that the majority of amateurs' negatives are developed in the presence of the "fragrant weed."

R. J. CHOLMONDELEY (Hythe).—Not knowing whether our correspondent means the retouching of cabinet heads or cabinet landscapes. If it be the former, Mr. Redmond Barrett's charge is, we understand, eighteenpence each, high-class work being assumed. If he means landscapes, he must write to Mr. Barrett, whose address is, 527, Caledonian-road, London, N.

R. BRISTOW.—Evidently you are under a misconception with reference to the "process block" portraits that sometimes appear in the illustrated periodicals. They are not all done from the original negatives, but from others made from specially worked-up portraits—often enlargements on bromide paper. In this way better results are frequently obtained than if the original were employed.

REDUCER.—1. To reduce with perchloride of iron, use it in the proportion of one drachm to six ounces of water. Bleach the plate, and, after washing, fix out the silver chloride formed with hypo. 2. One and the same.

H. WELLSMAN inquires if, when the copyright in a picture has expired, and photographs of it are published, he is at liberty to copy one of the photographs, as he cannot obtain the original picture to copy himself?—Although the copyright in the original picture has expired, there may be a copyright in the photographs of it, in which case reproducing one of them would render any one doing so liable to penalties.

NUMQUAM.—1. It depends entirely upon the effect desired and the formula used. 2. Yes; in conjunction with the preparation of the plates. 3. It is not usual to treat the plates with spirit. 4. Some workers adopt one method and some the other, according to the preparation of the films. 5. Quite a matter of taste, provided the plates are properly coated. Usually the plates are coated, and then placed in the drying box.

T. L. HART writes: "Can you give me the reason why my enamelled portraits lose their lustre after two or three weeks' standing? Some commercial enamels I have by me are almost as brilliant as when received several months ago."—The portion of print enclosed certainly has a dull surface for an "enamelled" print, but we cannot assign any reason for it, seeing that we are furnished with no particulars as to how the print was treated.

PROVINCIAL asks how professional enamellers treat the glass plates to prevent the prints sticking. He says he has tried wax and French chalk, and he cannot get on at all with the latter, but with the former he can, except that the prints have a smeary appearance from the wax, after they are taken off the glass.—There ought to be no difficulty with the chalk if it were well rubbed into the glass. The smears, when the wax is used, are due to imperfectly polishing the waxed surface. A little more care will overcome the difficulty.

J. C. HUGHES says: "I should feel extremely obliged to you if you can give me, through your correspondence column, a recipe for making a mountant for dry prints, and whether dextrine is injurious to a photographic image. 2. Messrs. Marion sell a mountant, a clear brown colour, for dry plates, which I wish to make some like."—In reply: 1. Starch is as good a mountant as can be used, whether for dry or wet prints. With regard to dextrine, see reply to another correspondent. 2. As we are unaware of the formulæ by which Messrs. Marion's mountant is made, we must refer our correspondent to that firm for its composition.

A. R. W. writes: "One of my assistants has unfortunately let one or two drops of sweet oil fall on a water-colour drawing I have undertaken to get framed. Although the oil was soaked up at once with blotting-paper, it has continued to spread in the picture. The picture is said to be a valuable one. I have tried to patch it up with water colours of the same tints, but it is repelled by the grease. Can you suggest anything to make the colour 'take'?"—If the grease be taken out no fresh colour will be needed, and this may be easily done in the following way: Take some *pure* benzol, and let one or two drops fall on the grease spots, and after it has remained a few seconds blot it off with perfectly clean blotting-paper. Repeat this treatment till the whole of the oil is removed. If the grease has penetrated deeply into the paper, it may be well to treat the back in the same manner as the front, that is, supposing the picture to be unmounted.

LONDON AND PROVINCIAL PHOTOGRAPHIC ASSOCIATION.—June 30, Annual General Meeting. July 2, Outing to Theydon Bois. 7, *Intensification.*

PHOTOGRAPHIC SOCIETY OF GREAT BRITAIN.—At the Technical Meeting on Tuesday, June 28, the subject for discussion will be *Latitude of Exposure.*

WEST LONDON PHOTOGRAPHIC SOCIETY.—June 25, Weybridge. Cycling division meets at School of Arts at half past two. Tea at "Hand and Spear," Weybridge.

PHOTOGRAPHIC CLUB.—Jane 29, *Plate and Film-changing Appliances.* July 6, *The Solubility of Photographic Chemicals.* June 25, Saturday outing to Watford. Train from Euston at fifteen minutes past two; Broad-street, forty minutes past one.

THE Duke of Newcastle and Mr. Gambier Bolton, F.R.G.S., start this week from Tunbridge Wells in the Duke's caravan, the "Bohemian," for a photographic tour in Kent, Sussex, and Hampshire. With two hand cameras always ready for "shots," and the large apparatus, which both carry, close at hand, they should return loaded with good negatives. Their journeyings will doubtless be watched with great interest.

BRIGHTON AND SUSSEX NATURAL HISTORY AND PHILOSOPHICAL SOCIETY (PHOTOGRAPHIC SECTION).—The next excursion of the Photographic Section will be on Saturday, June 25, to Berwick (Alfriston). Train leaves Brighton at fifty minutes past one. The next meeting will be held on Friday, July 1, at eight p.m., in the Librarian's Room, Public Library, Church-street. Subject: *Perspective as Applied to Photography; the Use and Abuse of Wide-angle Lenses,* Mr. Bedford.

JOURNAL OF PHOTOGRAPHY.

No. 1678. Vol. XXXIX.—JULY 1, 1892.

PRESERVATION OF SILVERED MIRRORS.

The production of mirrors by the deposition of metallic silver upon the surface of glass has now been practised for nearly half a century, and has greatly conduced to advances in the arts, sciences, and manufactures. Astronomical science in particular has gained much in the popularising of telescopes of large dimensions, that may now be had at prices infinitely less than when the costly specula, along with the still more costly achromatic object glass, alone held sway.

In photography the silvered glass mirror has proved of great utility as an optically perfect reflector. It need scarcely be pointed out that when the silvering is on the back of the glass, as must necessarily be the case if the tinfoil and mercury system be employed, the reflection is altogether imperfect and inadmissible for purposes requiring accuracy, on account of there being both a primary and a secondary reflection, the one from the silvered surface, the other from that of the glass.

A true optical reflector, such as that used in front of the lens for producing a reversed negative, must be silvered on the front surface, and that must be polished into brilliance by cotton wool and rouge, according to methods well known. The silvering itself is quite an easy matter, if practised according to the directions very carefully given in several of our Almanacs of a former date.

But what we desire at this time to draw attention to is the fact, that a layer of pure silver, exposed as it is to the action of the atmosphere, is very liable to become tarnished, and sometimes with considerable rapidity, by the deleterious gases continually present, in addition to the oxidation it would undergo even if the atmosphere were quite pure. Conversing on this subject with Mr. F. E. Ives, that gentleman mentioned his employment of a varnish composed of a solution of celluloid for such silvered surfaces, which, while it was infinitesimally thin and did not practically interfere with reflection, yet was so homogeneous as not to present the slightest break in its continuity, a test he employed for this purpose being the application of ammonium sulphide, which would immediately make its presence known upon the silvered surfaces. Mr. Ives had also tried collodion for the purpose, but found that, when greatly diluted, it had a disintegrated film. We, too, had frequently tried collodion as a varnish for silver, but, from our selection of a specially tough or skinny sample, and using an excess of ether, had not found any disadvantage.

Celluloid is readily soluble in amyl acetate, and this is the solvent that must be employed for the purpose in question. It is imperative that the solution be exceedingly thin, and also that it be carefully filtered previously to its application to the mirror, which, too, must be well dusted before it is coated with the varnish. No heat must be used.

In addition to the value of such a varnish as this, when applied for the protection of the reversing mirror of the photographer, it seems, so far as we have tried it, not to interfere with the definition of a silvered telescopic mirror, and, if further trials on delicate star tests should bear out our first impression, it may prove of utility in the employment and preservation of large reflectors, which entail a certain amount of trouble in re-silvering when the metal gets worn off by the polishing necessary to keep it clean.

THICKNESS OF FILM.

The opinion expressed in the course of the discussion on latitude of exposure at the Technical Meeting of the Photographic Society of Great Britain on Tuesday night, that a thick film of gelatino-bromide of silver allows of greater latitude in the exposure is, we believe, largely if not generally held. A little reflection, indeed, will show that the penetrative power of the light is necessarily determined by the quantity of silver salt held in the film, and consequently it is easy to realise that in the case of long or abnormal exposure the high lights and what we shall call the middle lights penetrate the whole of a thin film, or one comparatively poor in silver, far more readily than a film holding a larger quantity of silver.

Perhaps this effect may be more clearly understood and appreciated by the simple experiment of holding side by side, in the sunlight for a minute or so, two plates, one with a thin film of bromide, the other with a thicker film. On examining the backs of the plates after the exposure, it will be perceived that, while the surfaces of both plates are equally as dark, the back of the thin plate is much darker than that of the thicker one. In the case of over-exposure in the camera the penetrative power of light, although its action is not visible to the eye, is somewhat analogous in its effect.

The colour of gelatine plates produced by the presence, in more or less quantities, of iodide of silver in the film, is also supposed by many to assist the film in resisting the penetration of the light, although, in point of fact, the film itself may, as regards its quantitative nature, be undoubtedly thin. This theory is plausible enough, taking into consideration the comparative insensitiveness, if not inertness, of iodide of silver. Silver iodide enters into the composition, although only minutely, of the most rapid plates, and, employed in films in which so liberal a quantity of bromide is present as to constitute an admittedly thick coating, is probably capable of assisting to allow of a material expansion in the latitude of exposure as well as of minimising the dreaded phenomenon of halation. Indeed, a thickly coated film containing a good

quantity of iodide is held by many able experimentalists to fulfil both requirements far better than many other special devices. Here, then, is a hint for those plate-makers who are anxious to meet modern requirements under those two heads.

It is singular that the plea for plates admitting of greater latitude of exposure than those now obtainable should go hand in hand with that for plates that will prevent halation. We have heard it stated that both the complaints here implied are to be traced to the abnormally thin films with which emulsion-makers are now said to coat glass and celluloid. Avoiding for the moment any consideration of this point, we may note as a fact that in the earlier gelatine dry-plate days restricted latitude of exposure and halation did not seem so commonly complained of as now. This leads to the supposition that in those times much thicker films were vouchsafed to us than now. Is that so?

UNACCUSTOMED DEVELOPERS.

It is now many years since Mr. M. Carey Lea published a series of most elaborate researches into the varying action of different developing agents, many, if indeed not most of which had been hitherto unsuspected of the possession of any developing power. Although at that time none of the numerous substances tried exhibited any real advantage over pyro or ferrous oxalate, practically the only two developers then employed, more than one of them gave promise of better things if only the proper conditions of working could be found. Although we failed to corroborate in their entirety the results obtained by Mr. Carey Lea, the reason was probably to be found in the fact that, while our repetition of his experiments was made upon gelatine films, his original researches were made, if we remember rightly, with pure silver bromide spread upon paper.

At the present day, when paper is so generally employed, and developed prints are an every-day production in every laboratory, amateur or professional, it does not seem unlikely that some of these almost-forgotten developers might be found to have their special uses, either in rendering some particular class of tones or in dealing with negatives of some peculiar quality. For instance, while the prevailing tone of developed prints is usually found to range between neutral black and various shades of grey, there is an undoubted leaning towards tones of a warmer character, either brown or red, even to the *terra-cotta* tint known as "red chalk" or Bartolozzi. Again, different brands of paper, when used with any given developer, are often found to give results varying with the character of the negative, one paper favouring thin negatives, while another gives better results with an image of considerable vigour.

Now, in Mr. Carey Lea's exhaustive description of the behaviours of the different solutions tried by him, the colour as well as the relative vigour of the developed images were the points to which he attached the greatest importance, rapidity of development, freedom from fog, or abnormal reduction, and similar characteristics being made to occupy a secondary position, as being subject to modification by very slight causes. In the development of paper positives these two points are the ones which may be said to entirely control the character of the result, hence it is that Mr. Lea's articles of upwards of a dozen years ago become well worth reference at the present time, in view of the possibility already hinted at, that they may open up fresh methods of development available in connexion with our modern processes.

Of the large number of substances of widely different character "exploited" by Mr. Lea, undoubtedly the most interesting group was that of the ferrous salts, mostly of organic acids, to which especial attention was devoted, owing to the fact that it was from that particular group that the then newly introduced ferro-oxalate developer had been evolved. In practice, however, though most of the ferrous salts were found to possess developing powers, none except the oxalate proved to be of any real use as substitutes for the methods already in use, those that were readily soluble being generally the worst in this respect, while those which necessitated the employment of some other agent, such as potassic oxalate, for their solution, were open to the suspicion that any good effect might really be due to the formation of ferrous oxalate or other salt.

Some of the salts were, however, spoken of favourably as being worthy of further investigation under different working conditions, foremost amongst these being ferrous borate, tartrate, and sulphite; while, speaking without direct reference to the articles, if we remember rightly, the citrate, which soon afterwards became a recognised developer, especially for chloride films, was passed over with comparatively slight mention.

The borate developer was mentioned as in every way the one that had most favourably impressed Mr. Lea, though, again, speaking from recollection, its finest results were obtained when used in combination with oxalate of iron. Its general characteristics were, however, vigour of development and quality of colour, and our recollection of its behaviour with gelatine films is that it gave pleasing brown tones of a "sepia" character, and entirely free from the objectionable greenish tinge so frequently associated with brown tints.

Of course it must always be borne in mind that the colour of a film or image may be entirely different when viewed by transparency, and backed up by paper respectively; and that, therefore, the colour obtained by us might not be available for positive purposes. At the same time it should be also borne in mind that the colour of the positive by reflected light, *i.e.*, a paper or opal print, is very greatly affected by the thickness of the deposit, and that, though an image dense enough to be viewed as a transparency might be wholly useless when backed up by paper, still the colour under the latter condition would be favourable if only the density were considerably reduced. For sepia tones in bromide prints the borate developer of Mr. Carey Lea, either in its entirety or in combination with ferrous oxalate, might be worthy of a further trial.

In connexion with the ferrous nitrate developer there was nothing special to mention, except that it offered the chance of a combined physical and chemical developer; or, in other words, could be used for either wet or dry plates. Its actual application in this form had not, so far as we remember, been successfully made; but its possibility was demonstrated, and, as Mr. Lea pointed out, such a combination would constitute an ideal developer. This, again, may be worthy of further attention on the part of our experimentalists.

The sulphite developer was another that was very favourably mentioned, though, if we are correct in our recollection again, it was formed by the simple admixture of sodium sulphite and ferrous oxalate in Mr. Lea's experiments, while in our own we dissolved recently precipitated oxide of iron in excess of sulphurous acid. Formed in this manner, it makes a pale-green solution, which keeps well and acts as a somewhat energetic developer, giving markedly warm tones of the "red-chalk" character, especially with collodion emulsion; and, what is of greater importance, the red image so obtained can be toned with gold in precisely the same manner as a silver print.

This solution may be with very great advantage combined with ferrous oxalate in varying proportions, according to the colour desired; indeed, it makes a most admirable renovator for spent ferrous oxalate, and such a revived solution is particularly well adapted to the development of prints.

DUST.

We have dealt with the evil effect of dust on portrait and landscape lenses, but in modern photography we have to count with microscopes, telescopes, and spectroscopes, in connexion with which also the dust evil is capable of working considerable mischief. A good photo micrograph cannot be secured unless the lenses are scrupulously clean, and especially is this so when working with the eyepiece. To ascertain whether a particle of dust, that is perceptible in the illuminated field of view, is on the objective or the eyepiece, the latter should be revolved on its axis: if the spot move, its location is the eyepiece; if it remain stationary, it must be sought in the objective. In any case, it must be removed before work commences.

We need not discuss telescopically hurtful dust, as that branch of photography is only employed in a few and those skilled hands, but a word about the spectroscope may be written. To those who use this instrument with the eye alone, few things are more annoying than to find that a spot of dust of some kind has settled upon the knife edges of the slit; far more troublesome is the presence of such a particle, as, until removed, it is the cause of a permanent streak from end to end of the spectrum—a disfigurement that would be particularly annoying when the negative was the result of labour and time. We mention it here only to name a remedy that was recently given by a well-known astronomer. Those familiar with this "matter in the wrong place" know how troublesome it is to get rid of. The remedy is a quill toothpick—one that has been rubbed with the teeth is better even than a new one.

We dismiss our consideration of the connexion between dust and apparatus by saying that in the putting away of all apparatus—lenses, portrait, landscape, microscopic, spectroscopic, and woodwork—more injury is, perhaps, done by omitting to remove dust than by all other causes together. Where the possessions of a photographer are one lens and one camera, or a score, the most scrupulous care should be taken each day they are employed to see that they are put away perfectly free from dust. Many hundreds even of dry-plate negatives have their qualities greatly marred by pinholes of all sizes, caused by dust that has gained access to the camera or slide. To the trained eye a pinholey negative always suggests untidiness, the enemy to consistent uniform excellence.

There is, however, another dust cause for pinholes that is too often ignored notwithstanding the great care used by the makers of dry plates to see that they arrive at the hands of the user in as nearly perfect a state as possible; particles of dust, or splinters of glass, abrasion of packing paper, and so on, are bound to be seen occasionally on the plates, and every plate should be carefully swept with a broad camel's-hair pencil before being placed in the slides. Those who do not adopt this plan will be surprised to find how much unexpected dust is capable of removal with advantage in this direction.

Before concluding our remarks in a succeeding number, on what proves to be a very large subject, we wish to point out as emphatically as we can a dust effect by which great mischief is continuously being produced. We refer to the simple matter of framing photographs. "Oh, it is only a photograph, and we want a cheap frame" is a very familiar cry; but, be the frame as cheap as it may, every photographer who has the dignity of his art and its reputation for stability at heart should insist upon dust being excluded from even the cheapest frame by the simple expedient of pasting the glass to the frame in the well-known way. We have seen, we can truly say, scores of pictures, greatly valued by the owners, which it was desired to know how to restore, as they were "fading." It was most difficult to persuade the owners that the "fading" was nothing but dust, dust in fact that had gradually entered, as it will do, through the finest aperture or chink. All pictures framed without the protection we allude to will become altered more or less by dust deposit to the injury of the picture, not to speak of its gradually increasing disfigurement. Yet such protection is by no means common; we should not like to state the smallness of the proportion in which we should estimate it is carried out. Suffice it now to say, we emphasise in the strongest manner possible the need for this protection for preserving photographs in their pristine beauty and chemical integrity.

Photography in Japan.—We are pleased to gather from the annual report of the Photographic Society of Japan, a portion of which we print among our Society intelligence, that that Society now boasts the respectable total of 140 members. From this we take it that both the Society itself and photography generally must occupy a tolerably well-established position in Tokyo, a result no doubt largely brought about by the efforts of Mr. W. K. Burton.

Quite Another Thing.—In a recent Continental note we remarked, in reference to the Paris Photographic Exhibition, that "French firms appear to give it a very hearty support, which may in some degree account for the coldness with which it has been treated abroad." We meant something altogether different of course, the word "atone" being intended for "account." A good French friend in Paris has drawn our attention to the error, for the opportunity of correcting which we are obliged to him. The *entente cordiale* between the photographic press of each country is therefore in no danger of being strained or threatened.

Photography in Parliament.—Among the candidates for the honour of a seat in the Imperial Legislature is Mr. W. J. Lancaster, the well-known maker of photographic apparatus, of Birmingham, who is contesting one of the divisions of that town. Glancing down the list of candidates, we observe the names of many amateur photographers. Let us hope that some of them will be successful, for, on the principle that a fellow feeling makes us wondrous kind, it will then be possible occasionally to get a question of photographic interest put to the Government on, say, such an iniquitously foolish law as the new methylated spirit regulations, or on other matters of interest which occasionally affect the comfort and convenience of the estimated quarter of a million photographers throughout the country.

Sensitiveness as a Factor in Exposure Calculations.—Dr. Vogel's experience of the increasing sensitiveness of gelatine plates if kept for any length of time, as referred to in our "American Notes" last week, suggests to us a point possibly of some importance in connexion with accepting the ascertained photometer speed of plates as a constant factor in exposing. If plates really do increase in sensitiveness—and there certainly seems some evidence to support the theory—then it is probable that their photometer speed can no longer be regarded as a constant factor if the particular batch of plates tested be kept a certain length of time between the moment of testing and the moment of exposure. It is no uncommon thing for unexposed plates to be kept many months before exposure. We

suppose that in that case it would be recommended to test the plates as soon as possible before using; but how would this get over the alleged difficulties of different batches of plates, and different plates in those batches, varying in sensitiveness, although the contrary is supposed to be the case by makers and users alike?

The Kew Method of Testing Lenses.—At the Royal Society recently, a paper by Major Darwin, "On the Method of Examination of Photographic Objectives at the Kew Observatory," was read. The paper describes the method of examination of photographic objectives which has been adopted at the Kew Observatary, chiefly on the recommendation of the author. In selecting and devising the different tests, Major Darwin acted in co-operation with Mr. Whipple, the Superintendent of the Observatory, and was aided by consultations with Captain Abney. Among other particulars we learn that the principal focal length is found by revolving the camera through a known angle, and measuring the movement of the image of a distant object on the ground glass; with the testing camera it is so arranged that an angular movement can be given with great ease and accuracy, and that the angle is such that half the focal length is directly read off on a scale on the ground glass. The observation is made when the image is at a point some fourteen degrees from the axis of the objective, and it is proved that the focal length thus obtained, even though it may not be identical with the principal focal length as measured on the axis, is, nevertheless, what the photographer in reality wants to ascertain. This test for distortion depends in principle on ascertaining the sagitta or deflection in the image of a straight line along one side of the plate. It is shown that to give the total distortion near the edge of the plate would not answer practical requirements, and that the proposed method of examination does give the most useful information that can be supplied. Definition is found by ascertaining what is the thinnest black line the image of which is just visible when seen against a bright background. It is shown that this is the best method that could be devised of measuring the defining power of an objective, and that it is not open to serious objections on theoretical grounds. The test for astigmatism is performed by measuring the distance between the focal lines at a position equivalent to the corner of the plate, and by calculating from the result thus obtained the approximate diameter of the disc of diffusion due to astigmatism.

OBSOLETE PROCESSES.*

No. 5.—The Taupenot Process.

In the article on the old, or original albumen process, it was mentioned that most excellent results could be obtained with it, but a long exposure was necessary; also that great precautions had to be taken in the preparation of the plates, in order to obtain a film free from dust spots; and, furthermore, there was the inconvenience of the plates having to be kept perfectly horizontal until they were dry, for, unless this was done, an even film could not be obtained.

The process now to be described is, to an extent, a modification of the original one, and was named after its originator, the "Taupenot Process," or, as it was more familiarly called, the collodio-albumen process, inasmuch as it was a combination of both the collodion and the albumen processes. There were two films, both of which had been sensitised in separate silver baths, the one collodion and the other albumen. Although more operations were involved in the preparation of these plates than in the older method, they were, on the whole, found to entail less trouble and care, as they could be dried in a vertical position, and the drying accelerated by heat. Added to this, the plates were more sensitive, and developed more easily, while the results, if not superior, were at least equal to those obtained with albumen alone. Therefore it is not surprising that soon after its introduction the original method was seldom practised, that is, for negatives.

In all the older processes on glass, the greatest care had to be bestowed on the cleaning of the glass, and essentially was this the case in the one under consideration, for not only with an imperfectly cleaned plate was there a liability to stain, but there was as well the almost certainty of a blistering of the film during the development. Indeed, in the earlier days of the process, blisters were one of the greatest troubles encountered in its working. Tripoli and alcohol, or tripoli and ammonia, were the most favoured cleansing agents.

The plate, having been cleaned, was next coated with iodised collodion. The mechanical condition of the collodion used was really of more importance than its chemical nature. One of a very adhesive character was necessary. That usually employed was such as was in use for wet collodion, after it had been iodised for some months and had become too slow to use for its original purpose. When the film had well set, it was sensitised in the ordinary silver bath—thirty grains of nitrate of silver to the ounce of water. The state of the solution was of minor importance. A bath that would yield foggy, or otherwise inferior, negatives if the plates were used direct, would still do quite well for collodio-albumen. After the collodion film was sensitised, it was well washed in several changes of water, and finally rinsed under the tap. After closely draining, the plate was ready to receive the iodised albumen.

The formula for the iodised albumen, like most others, varied with different workers. This is the one we generally employed ourselves:—

Albumen	12	ounces.
Iodide of potassium	1	drachm.
Bromide of ammonium	15	grains.
Liquor ammoniæ	1½	drachm.
Water	3	ounces.

With sufficient iodine to give a pale sherry tint. The whole was then whipped to a stiff froth, as described for the albumen process a fortnight ago, and allowed to subside. The liquid portion was then filtered, either through sponge or fine muslin. The albumen was applied in the following way:—A little was poured on the upper portion of the drained plate and allowed to flow over it in an even wave and off the other end into the sink, carrying what superfluous water there was before it. After draining for a few seconds, a fresh lot of albumen was applied, and this was flowed backwards and forwards over the plate for a minute or two, so that it might soak into the collodion film. The excess of albumen was then poured off into a vessel, to be used again as the first application to the next plate. The plate was then reared up on end to dry, either spontaneously or assisted by heat—the latter was most general.

When the surface had become partially dry, the plate was subjected to heat, usually by holding it before the fire until it became as hot as the hand could well bear. Strongly heating the plates at this stage was found to be a great preventive of blisters. In connexion with blisters, it may as well be mentioned here that it was a very common practice to give the plates a preliminary coating of dilute albumen, and drying, before the collodion was applied in the first instance. This thin substratum, though increasing the manipulations, secured an immunity from the trouble, and therefore was invariably adopted by some workers. In this state the plates would keep good for years. Up to this stage the plates could be prepared in open daylight, as any effect that the light might have upon the sensitised film was destroyed by the iodised albumen, which also obliterated any bad effects from a disordered silver bath.

The sensitising bath, like that used in the albumen process, was the aceto-nitrate of silver, but somewhat weaker—thirty grains of nitrate of silver and a similar proportion of acetic acid to the ounce of water was the strength usually employed. The time of immersion was short, not more than a minute or so. When the plates were taken from the bath they were thoroughly washed, first in dishes, and finally under the tap. They were then dried spontaneously, either in a drying-box or, more often, on the shelves of the dark room. The sensitised plates would keep good for a month or two; but, if they were treated with a dilute solution of gallic acid before they were dried, they would keep for a year or two.

With regard to the exposure, the plates were slow, though they were quicker than the original albumen ones. With a single lens, aperture, say, *f*-30, a landscape would require from five to fifteen minutes, according to the light. Here there was, with this process, considerable latitude allowable, and the best workers seldom, if ever, erred on the side of under-exposing.

* Concluded.

In the earliest days of the process a solution of gallic acid, with a drop or two of aceto-nitrate of silver, was the developer employed. Later on, pyrogallic acid superseded the gallic, and this is how it was used:—The exposed plate was first moistened with water. Then a plain solution of pyro—a couple of grains in an ounce of water—was flowed over the plate. In a short time this would bring out a faint, phantom-like image by reflected light, from which the correctness, or otherwise, of the exposure could be judged. If it had been rightly timed, the image would come out evenly, just as it does in a correctly exposed modern plate. When nearly the whole of the detail in the shadows was visible, the solution was thrown off, and another containing two grains of pyro to the ounce of water, restrained either with fifteen or twenty minims of acetic, or half a grain of citric acid, was flowed over the plate. It was then poured off and a drop or two of a solution of nitrate of silver added. It was then reapplied, and the development, or rather intensification, continued until sufficient density was obtained. If stains appeared on the surface of the film, as would sometimes be the case with a prolonged development, they could be rubbed off with cotton-wool under the tap.

As with the albumen process, so with this one, the image was of a highly non-actinic character, and the negatives of many novices were spoilt by over-development. If, by chance, the plate was under-exposed, detail was coaxed out by using a warm or, if necessary, a hot solution of plain pyro. If over-exposed, a large proportion of silver was employed with the acidified developer. The fixing solution was one of hyposulphite of soda, of about the strength now employed for gelatine plates.

The results obtainable with the collodio-albumen process are perfectly familiar to our older readers; so, to them, no comment is necessary. To our younger ones we may say that the process has yet to be invented that will yield finer negatives—that is, in the hands of those proficient in its manipulation.

CONTINENTAL NOTES AND NEWS.

An Old Friend in a New Dress.—Some ingenious German knight of industry has, it seems, been lately exploiting a mysterious and wonderful product, which was said to be of remarkable value as an accelerator if used as a preliminary bath before development. The substance was given the formidable name of monobrombrenztraubensaure! Dr. H. Vogel is reported to have submitted a sample of it to the cold and impartial scrutiny of analysis, and to have pronounced it to be nothing more and nothing less than our old friend, hypo!

Coloured Transparencies.—M. Meunier-Pouthot is said to be introducing commercially a plate which, with a special kind of toning bath, of which no details are to hand, allows of the deposit being easily coloured either yellow, yellowish brown, reddish brown, plum colour, violet, red, blue violet, indigo blue, or greenish blue as may be desired. All these colours are said to be obtained with one toning bath, much, if not all, depending upon the time of exposure and toning. Possibly, by local toning, this process is susceptible of yielding part-coloured lantern slides and transparencies.

How to Tell Whether a Plate has been Exposed or Not.—M. Papazogli, of Vaud, suggests treating the corner of the plate with the developer; if the plate darkens, it has, of course, been exposed; if not, the colour of the deposit is unchanged. It is also suggested that this is a ready means of ascertaining whether a plate has been over or under-exposed. The efficacy of this highly ingenious method, which we have all unaccountably overlooked up to now (save and except M. Papazogli), is somewhat discounted by the circumstance that, though the margins of a plate may not darken under the developer, the centre may, nevertheless, have been exposed, and thus the door is opened wide for error. So, once more, *cui bono?*

An International Photographic Exchange.—Messrs. Hamfeld & Stahlberg, editors of the Helsingfors journal, *Cameran*, are issuing a polyglot circular to Swedish, Finland, Russian, German, French, and English amateurs, asking them to send to Messrs. H. & S. ten or more unmounted prints from their negatives, when they will receive in exchange an equal number of the same-sized prints—of course, of different subjects. Thus the amateur has a ready means of making an international collection of amateur work from different parts of the world. Messrs. Hamfeld & Stahlberg propose to open branches in St. Petersburg, Vienna, Berlin, London, and New York. It is difficult to see what profit, beyond that accruing to pure philanthropy, awaits Messrs. Hamfeld & Stahlberg in their enterprise. If any of our amateur readers have received the circular spoken of, we should be glad to see it.

M. Villain's Coloured Positive Process.—In describing his process before a recent meeting of a French photographic society, M. Villain gave the following details:—Paper is floated on a bath consisting of

Water	1000 cc.
Bichromate of ammonium	50 grammes.
Metavanadate of ammonium	5 „

The paper is dried at a low temperature in the dark, and is then exposed under a negative until the details are well out, being next washed to remove the unaltered bichromate. The picture is now immersed in the colouring bath, which is maintained at a temperature of about 90° C. If, after "colouring," the whites are not clear, a warm bath of sodium carbonate, or a cold bath of lime carbonate acidified with hydrochloric acid, is applied. The colouring agents employed include artificial alzarine, isopurpurine, alzarine blue, alzarine black, green, orange, anthracene brown, and others. Combinations of these may be applied, and thus a large variety of tints obtained, all of them stable under the action of light.

ADVANCED PHOTOGRAPHIC WORK FOR AMATEURS.

II.

Having referred in a previous article to the making of the emulsion, and the coating and setting of the opal plates, we now come to the consideration of what is also a very important factor in the operation, viz., the drying of the coated plates.

Undoubtedly, since the advent of the gelatino-bromide process, perhaps there has been no greater stumbling-block to the amateur plate-maker than that of a handy and reliable method of drying his coated plates, for doubtless it has been at this stage that failures have arisen, and hence the dread many experienced workers in a small way have of tackling the making of their own emulsion.

From time to time quite a numerous class of drying boxes and contrivances have been suggested for the purpose, some of which are so constructed as to utilise gas as a warming agent to the interior of the chamber, but all seem to agree on the necessity of having a current of air freely circulating through the box. When such a box is at hand, the difficulty of drying is entirely overcome, but there is no need for any ordinary worker to refrain from undertaking the work we are considering on account of not having at his disposal a drying box. In the case of the emulsion we are dealing with, we have not an article of such exalted sensitiveness as a bromide emulsion, commonly met with in dry-plate practice or negative work. What we are dealing with is a printing-out emulsion of much the same sensitiveness to light as ordinary printing paper, and hence the same absolute precautions from every ray of white light during drying are not so imperative. This being so, there are many simple, homely ways whereby plates, coated with such an emulsion, may be dried without the aid of any of the so-called drying boxes or chambers, so necessary in bromide emulsion work.

I have said that in all the arrangements for drying plates of any description an essential element is that a current of air be made to pass over the films. Let this *desideratum* once be grasped and understood, and an enthusiastic worker will not be long in rigging up some homely arrangement for drying the plates. I may, however, describe three entirely different methods that I have seen adopted by some of my pupils for the drying of the same kind of plates we are considering. One very simple way adopted by a gentleman—who, by the way, is merely a lodger, and who, therefore, has not the entire control of a household—is by the utilisation of the fireplace in his bedroom, and, all told, this is perhaps as simple a plan as any that

can be arranged. Having coated a few opals, he opens the damper of the fire-grate, so that a current of air passes up the chimney. He then brings in a box about three feet long by twenty inches square, with both ends knocked out. This box is placed close up to the fire-place, and some clothes padded round the end, which he places against the grate. I have seen him utilise his "breeks" for the purpose. This long box acts like a tunnel, and the air rushes in and up the chimney in fine style. Plates coated with an emulsion as described will dry evenly and perfectly, in dry weather, in about four hours by this simple means. He generally so arranges to have the plates placed on the tunnel just about bedtime or after dark, and during the early hours of the morning he gets out of bed, and stows the opals away in grooved boxes. Another method employed by an ingenious amateur is on the same lines as the above; only, instead of using a long box, he utilises his large 12×10 camera. This he places, with the front out, up against the fireplace, and, having placed some sheets of brown paper to protect the inside of the bellows, he places his half-plate opals inside, and gets up in the early hours of the morning and merely folds down the focussing glass, over which he throws a dark cloth. After breakfast the plates are then removed to a store-box.

Another very simple way is the using of a grooved box of the same size as the plate coated. Out of the top and bottom of the box a long strip of the wood is removed; this extends the full length of the box. Over this apparatus a length of coarse muslin is tacked. When the plates are placed in the grooved boxes the lid is shut down, and after dark the box is placed on end in some place where a draught or current of air passes, such as an open doorway, or in front of a fire-place, as described. The muslin tends to prevent dust getting on the surface of the plates, but the plates take slightly longer to dry. However, it is quite a good plan. Either of the above methods may be adopted with a certainty of success provided a current of air be made to pass over the films. Do not be tempted to use heat in any shape or form, and when such simple means are adopted the drying difficulty is at once overcome, and we have on hand a supply of opal plates of about the same sensitiveness as ordinary albumenised printing paper, and all that remains to be done is to place the same in an ordinary printing frame in contact with a suitable negative to print in the shade, according to the requirements of the particular negative used. Of course the face of the opal cannot be inspected during printing like a piece of sensitive paper, but it is quite an easy matter to run a pilot alongside during the printing operation. This may be done by taking a negative of similar density and placing in contact with it sensitised paper, and when the one is up the other will be about right. A very little practice with each batch of emulsion will show the comparative sensitiveness of the opals to the paper used. It is well, however, to print deeply. On removal from the printing frame, the opals are treated in exactly the same way as ordinary silver prints. That is, they are first subjected to washing in several changes of water, they are then toned with a very weak acetate bath, which may be conveniently made up as follows, viz., one tube of gold, one ounce of acetate of soda, and forty ounces of water, prepared the day before, being used. When going to tone, add the same amount of water to the quantity taken from the stock solution as above, but do not tone just into the purple, for the film will dry at least three tints darker than the pictures appear when being taken from the fixing bath.

Provided the plates are evenly coated, and ordinary care exercised in the manipulation, the surface of the opals will be found to be quite evenly toned; but, should it be found that slight cases of irregularity are apparent, then a preliminary bath of weak alum and water will be useful. The plates are then fixed in a weak hypo bath, and, after careful and thorough washing, are set aside to dry, when pictures of more than ordinary beauty will be the result, and which will be sure to cause more admiration than any silver print on paper ever produced.

The opals may be finally mounted with a cover glass, having a cut-out mask or mount inserted between the film and the glass, and bound round the edges with lantern strips, or they may be framed as taste dictates.

An emulsion such as I have described comes in very handy in another way at times, for who has not among their collection of negatives a plate that would not be benefited by some dodging, whereby the dense high lights of the negative would be made to print more in harmony with the shadows and middle tints of the picture? Such cases are very frequently to be met with, and, as a rule, the treatment generally adopted is the flooding of the glass side of the negative with ground-glass varnish, or other similar material. When such is used, there is always the after-manipulation required in the removal of the varnish from the high lights by means of a scalpel, whilst the middle tints are left just to look after themselves, for it is not easy to deal with them when ground glass or some other semi-opaque substance is used to retard the printing of the shadow portions of a negative only. When, however, a worker has a small quantity of the emulsion referred to beside him, he has in his possession a most valuable medium for correcting such inequalities in a negative, and the application of such is an operation of much interest to those who desire to follow in a somewhat higher track than the mere printing of a negative just as it happens to turn out good, bad, or indifferent.

Some writers pooh-pooh the after-improvement of negatives in every shape and form, and condemn retouching and *all dodging* as outside the pale of legitimate photography, and even to such an extent was this carried that amateur photographic societies were beginning to make such strictures in their rules for competition that were simply absurd. In my opinion, every possible means should be employed to improve negatives, and so get the most pleasing results in the way of prints from them.

Here, then, is a very simple way of treating a negative that has over-violent contrasts. First, let the worker take a sheet of glass the same size as the negative, and having made it fast to the film side by means of ordinary gummed lantern strips (the object of this is to protect the film from any possibility of damage during the operations that are to follow), then let him take from his stock of emulsion, which, when melted, will be sufficient to flow over the glass side of the negative. Of course, this must be scrupulously cleaned. The operation, in fact, is just that of coating a plate. Having flooded the negative, it is set on a levelling stand, and in due course placed in the drying tunnel, and when dry is ready for exposure. We have now a negative with plain glass on the film side, and a coating of printing-out emulsion on the glass side. The negative is now placed in an ordinary printing frame, and a piece of black velvet or other suitable soft material placed over the sensitive coating of emulsion so as to avoid any damage to the film by pressure from the springs and back of the printing frame. But little consideration will be required to understand that when such a plate is exposed in a printing frame to daylight the shadows and middle tints will be impressed before the high lights are printed at all; and this is just what we require in such a case as we are considering—in fact, we print a partial positive image in close contact with the glass side of the negative, and the image so printed acts as a most beautifully perfect shield over those parts that it is desired to retard the printing of. When it is deemed that sufficient detail and density has been printed, all that remains to do is to fix the plate by means of an ordinary hypo solution. In doing this it is more convenient to apply such (after the plate has been washed under the tap for a minute or two) by means of a flat camel's-hair brush. This will prevent the need of placing of the entire negative in the hypo bath, and when such is gone about expeditiously the paper binding to the cover glass of the negative will be quite sufficient to protect its surface from damp. When fixed, a slight wash and after-application of an alum bath will finish the operation, and we have then performed one of the cleverest dodges in the way of doctoring a faulty negative that I know of. To those anxious to improve such negatives I say, Try it. T. N. Armstrong.

CLEAN NEGATIVES.

At a photographic meeting held just recently, and reported, mercuric chloride was recommended for the purpose of removing the iridescent stains frequently seen when developing, *with pyro*, old and stale gelatino-bromide plates; the words *with pyro* are used advisedly, the stain not making its appearance when an *iron* developer is used. The statement should not in my opinion go out to the public without qualification. If it be true that a solution of mercuric chloride will remove this stain, and it is not my invariable experience, it is far from being the best chemical for the purpose.

We are probably half way through with the development of a negative, when, hey presto! appears this demon stain, little or more, according to the quantity of ammonia used in the developer; further detail under these circumstances is not to be got, therefore we wash and fix the plate.

Now, to *intensify*—for that is what it means—with mercury, is not the thing to do yet, for it means clogging up the shadows of an already dirty negative. The thing to do is to clear away the stains first, and *then* intensify as follows:—Add a few drops of a saturated solution of red prussiate of potash to a weak hypo solution (half an ounce to the pint). The stain disappears very quickly. If the negative has not been allowed to dry, a tuft of cotton-wool assists the action very much; but it will be easy to over-do it, so that as

soon as the stain has gone remove the negative and wash thoroughly We have now a beautifully clear and clean negative, which will be *improved*, in most cases, by intensification with mercury. Colour and density will be satisfactory.

With regard to green fog, this is unquestionably removed by mercury treatment; but here, again, where is the advantage? Green fog I have not met with for some years, but if I remember rightly, it was never noticeable till after the negative was fixed and dried. Therefore, in the majority of cases, the negative was already dense enough, and needed no further intensification—in fact, would be spoiled by such treatment. If thought necessary to remove the fog, and I believe it was generally thought not to impair the printing qualities of the negative, the bath already mentioned will answer every purpose.

J. Pike.

TELESCOPIC PHOTOGRAPHY.

About three years ago, I made several attempts to photograph distant objects, and a few notes of my experiments were published in the Almanac, along with an engraving from one of my negatives. The lens I used was a very fine two-inch telescopic object glass, by Wray, of twenty-five inches focus, and a No. 2 microscopic eyepiece by Zeiss. I found, however, that such an eyepiece was not at all suited for the purpose. The image on the screen was very bright, but there was always an amount of fuzziness which made the negatives taken with it very imperfect as to sharpness. I had done nothing farther in the matter until my attention was again directed to it by the notices and correspondence in regard to Mr. Dallmeyer's proposed tele-photographic lens. I have not seen any of these lenses or any of the photographs taken with them, nor have I further information as to what had long ago been done by Dr. Hugo Schroeder other than what has appeared in his letter in this Journal.

When I was experimenting with the Wray objective of twenty-five inches focus, I found that when the camera was placed on the western shore of the Gareloch at Rahane, which is just about a mile broad at that place, the field of view given by the combination I was using was, on a quarter-plate, only sufficient to enable me to get into the negative one-half of the steamer *Gareloch*, which was then lying at Balernock Quay on the eastern or opposite shore. This seemed rather too great a magnification for ordinary landscape photography even of a moderately distant object, and in the experiments I have just made I have adopted a much shorter apparatus. I came into possession the other day of an old photographic portrait lens which belonged to the late Dr. John Thomson, R.N., a former President of the Edinburgh Photographic Society, and I determined to use it as the objective to form the image, which I prepared to magnify in the camera. This lens has an equivalent focus of about eight and a half inches, and the combinations are about two and one-eighth inches in diameter. I was at first somewhat doubtful if it was actinic, as it had evidently been made at a very early date. I found, however, on trial that it was all right as regards its actinism. Now, having got my objective, in what way was I to magnify the image it gave me? A Huygbenian eyepiece would not do. I had settled that by my previous experiments. I did not believe in the Barlow achromatic concave amplifier which Mr. Dallmeyer uses. I had, however, in my microscope box a very fine No. 4 projection eyepiece by Zeiss, of Jena, which I knew was perfectly corrected for the chemical ray. I have not noticed in all the writing and notices which have appeared recently that any one has used, or suggested the use of, such an eyepiece for tele-photography. I felt sure that I had found exactly what I required, and I at once made a rigid box camera, a good substantial one, and, although it is made out of a few scraps of old packing-boxes, I have stained it with bichromate of potash, exposed to sunlight, and then varnished, and I should not be at all ashamed to show it to that learned body, the Convention, when they meet in our modern Athens next month. The baseboard of the camera is exactly eighteen inches long. From the flange into which the portrait lens is screwed, to eye lens of the projection eyepiece, is 7½ inches, and from the eye lens to the ground-glass screen of the camera is 0½ inches. I find that this distance is required to give me a sufficiently large circle to fill or almost fill the breadth of a quarter-plate.

Yesterday evening, between seven and eight o'clock, I exposed three quarter-plates, and these I have sent to the Editor that he may see the quality of the definition given by the combination I have described. Each plate got ten seconds' exposure. These are the first plates I have exposed, and were all three first shots. I find, upon measuring the size of image given by the portrait lens alone, and also the same image when used along with the eyepiece, that the camera gives me a magnification of exactly six times. This was ascertained by turning it to a signboard and measuring the relative length of the two images; or, again, the magnification may be arrived at in another way. I found, on calculating the equivalent focus of the projection eyepiece by Cross's formula, that it was equal to a single lens having a focal length of 1·46 inches, or, as nearly as may be, one and a half inches. Dividing the focal length of the portrait lens by one and a half we get the figure six. I think I am right in assuming this method to be very nearly accurate, because the distance of the eye-lens from the screen is just about ten inches, the *assumed* normal focal length of the human eye.

One thing seems to be a most important factor against the use of combinations of lenses for photography, and that is, the difficulty of getting more than one focal plane into focus. We know that, whatever may be said to the contrary, it is impossible to see more than one focal plane in the microscope, and the same defect, if it may be termed so, is forcibly apparent when focussing with the combination I have described above. What, however, one looks for, and should strive to obtain, is such a reasonable arrangement as not to render the want of sharpness on the resulting photograph unpleasantly conspicuous to the eye. Of course, one need not be restricted to a quarter-plate in such a matter. It is only necessary to increase the distance of the plate to get any reasonable size covered. I should have liked much better had my portrait lens been of greater focal length. One of about twelve inches equivalent focus would suit very well. Taking, however, that I have, and multiplying its focal length of eight and a half inches by six, the magnification used, it is easily seen that with the short camera I used I get, practically, a picture the same as if I had used an ordinary photographic lens of six times eight and a half, or fifty-one inches focus.

Procella.

OLD SILVER PRINTS.

II.

Before we place our prints, after toning, in the hypo solution, all the free silver nitrate and salts soluble in plain water have been got rid off, and there only remain those that require chemically decomposing for the hyposulphite to act upon. This it does by dissolving the chloride after changing it into hyposulphite of silver, which is only quite soluble in a strong hyposulphite of soda solution and water. Some albumenate of silver has also to be removed. This is somewhat more difficult to thoroughly effect; in fact, it very often is left in the prints. *No* silver should be found in the whites of a properly finished print.

The method of doing it is to use a tolerably strong fresh solution of hyposulphite of soda for a sufficiently long time, or preferably two baths of the same strength, with or without the addition of a little ammonia. After the action of the hypo on them, we have the prints saturated with salts that are soluble in ordinary tepid water; and if the prints are removed singly to dishes where they can be alternately washed and pressed for a few hours, with a constant change of tepid water, they will in all probability be freed from anything prejudicial to their permanence. The final rinse or two may be in tolerably hot water with advantage.

Prints will be much brighter and better for a short washing, of not more than two hours or less; after a more prolonged soaking, the long immersion invariably reduces the gloss of albumen prints, and does not conduce to their permanency—rather otherwise. The wet washed print should be *tasteless and odourless*; if any metallic taste remains or any odour is distinguishable, it may be concluded the prints, for some reason or another, have not been properly fixed or washed. It is surprising how seldom the process of fixing and washing is properly done, even by men whom one would have thought to be thoroughly versed in the matter. A very usual way of working is, after a wash after toning, or even without it, to gather the prints into a bundle and plunge them all together into a small quantity of hypo bath; to separate them afterwards. It stands to reason, if a large number have to be separated, those last moved will not have received the same amount of fixing as the first did; it may make from three to five minutes' difference, a consideration when ten or fifteen minutes is the time allowed in the hyposulphite solution. They are then once more gathered into a bundle, pressed with the hands, and plunged altogether into clean water, to be again separated. It is very probable that, by this style of working, some of the prints do not get separated, and consequently neither properly washed nor fixed; the only excuse offered, it economises the time, but if it does, which is questionable, it is at the expense of the prints.

Another risky proceeding, with regard to permanence, is fixing several batches of prints in the same hyposulphite solution one after the other. The last batches, in all probability, are not fixed so well as the first; a little extra time being given will not make up for deficiency of solvent power, especially if the hypo bath was weak to begin with. Weak baths have been, time after time, recommended

to prevent the blistering of albumen paper, but I am firmly convinced that weak baths will not properly fix any prints, no matter how long they remain in them; time is not a substitute for strength, for the objectionable salts in the prints are almost insoluble in weak hypo, and this, with a low temperature, as very often happens in winter, practically leaves the prints unfixed. Temperature is an important factor through all the processes, none of them working smoothly and well if it is very low. Very high, say 100° F, has also its disadvantages by making the prints less brilliant; I do not allude to the final washing, but to the toning and fixing. I have found that the presence of hyposulphite alone, in a properly fixed print, is *not* detrimental if the prints are kept dry, and not particularly so if they are not specially cared for in this respect. To ascertain this, I prepared two prints carefully in the same solution, at the same time, washed and dried them, afterwards dipping one for a few minutes in a twenty per cent. solution of hyposulphite of soda, again, just rinsing, drying, and fastening each up in a bottle suspended in the full light, out of doors, for a long time. There was not the slightest apparent difference in either; afterwards a bit of damp blotting-paper was introduced, and after some time had elapsed no change had taken place, and the experiment was dropped. In all probability the damp would, in course of time, have produced some damage, and to a greater extent with the one containing hyposulphite than the other; but what prints would not suffer if continually exposed to a damp atmosphere, either with or without special chemical agents in contact with them? Imperfect as the experiment was, it satisfied me that hyposulphite of itself is not the bugbear it is made out to be in connexion with silver prints, and I certainly think the lasting qualities of the many old prints we see support this opinion.

When hyposulphite of soda is a *real enemy* is during the time the prints contain free silver nitrate, when the *least trace* will not only produce stains, but utterly ruin the pictures, if the usual alkaline methods of toning are employed. If a yellowish glare appears on the prints in the toning bath, it may be certainly concluded that hyposulphite of soda has somehow or another contamiuated it, when the merest trace is sufficient to do this and to spoil a whole batch of work. It will be noticed that, if this occurs, it will be almost impossible to wash out a peculiar sulphur odour that is very perceptible when the prints are warmed, as well as when partially dry. It is a remarkable fact that such an infinitely small amount of hyposulphite of soda should have the power of producing so great an effect. The yellowish glare alluded to seems to be sulphur, but the *mere trace* of hypo producing it could scarcely be sufficient to supply enough to spoil an almost unlimited number of sheets of prints. I think this is a matter that it would be useful to investigate. If the deposit is not sulphur, what is it, and where does it come from?

EDWARD DUNMORE.

EARLY PHOTO-MECHANICAL PRINTING PROCESSES.

[Journal of the Photographic Society of India.]

UNDER the heading *Processes before their Time*, the writer of an editorial note in THE BRITISH JOURNAL OF PHOTOGRAPHY for April 29 remarks that the method of breaking up the tones of a subject into lines or dots to obtain a printing plate was first practised and patented by Fox Talbot forty years ago, and that his photographic process is practically the same as the "photogravure" methed now practised. He also points out that half-tone blocks, and good ones, were produced by Pretsch in 1855, and that as far back as 1866 Bullock Bros. prodnced photo-lithographs in half-tone quite equal to those now made. He asked why, therefore, did these processes remain dormant so long? and gives his opinion that the reason is, because the processes were introduced before their time; their valne was not recognised, and therefore they were not appreciated. This may be to some extent true from the fact that the full value of photography for reproduction was not then known, but the real reason of the delay in recognising the merits of the old processes is, more probably, that they were all of them deficient in some point, the want of which made them nseless for really practical work. In the later methods these missing links have been supplied, and the defects of the old processes having been overcome in various ways, they have been put on a really practical footing, and as soon as this was the case they have been taken into use. For instance, Fox Talbot's early method of photoglyphic engraving contained all the germs of the photogravure process; the resin ground, the negative chromo-gelatine image, and the etching with perchloride of iron were much the same as at present, but it failed for the same reason that all the old carbon processes failed, by having a quantity of soluble or unchanged gelatine at the under surface of the exposed image, so that the etching fluid penetrated to the copper underneath even the densest parts of the gelatine image, and it was not until Klič applied Swan's method of carbon printing to the photoglyphic process and etched through the *developed* image that really practical results were obtained, and now the obtaining of a well etched plate with perfect gradation from the most delicate lights to the deepest shadows is a comparatively simple operation, which it certainly was not with the original process, in which it was exceedingly difficult to keep the gelatine film down on the plate, and to obtain full gradation in the etching.

It was the same with the various methods of photo-galvanography, or photo-electrotype—they were very good, but not thoroughly practical; they took a lot of time and required a great deal of hand work, and consequently they have been largely superseded by the etching processes.

Again, Poitevin's method of printing off an exposed gelatine film had all the elements of the present photo-collotype processes, but was quite unworkable in its early form, and it was not until the principle of sunning the exposed gelatine film from the back was introduced that it became practical.

Then, as regards half-tone block processes, no doubt various half-tone block processes, some of them good ones, have from time to time been brought forward by Pretsch, Placet, Dallas, Woodbury, Ives, and many others, but nothing very practical was done until 1883, when Mariot enounced the principle of graduated diffusion of the lines and dots by which the image was broken up, and Meisenbach about the same time brought out his "autotype" process of photo-block printing, which depended on this principle of diffusion by the nse of ruled screens placed in front of the sensitive plate, as noted in my paper on *Half-tone Photo-block Processes*. Since then the latter method, and modifications of it, have taken possession of the field, and naturally, as soon as publishers and newsvendors found that they had a really workable process of the kind available, they have hastened to make use of it, somewhat to the detriment of the older and more artistic woodcut. It is not so much that these new reproductive processes were not wanted before as that they were not available in a really practical form as they now are.

COLONEL J. WATERHOUSE, S.C.,
Assistant Surveyor-General of India.

THE LATE LEWIS MORRIS RUTHERFURD.

WE are sorry to learn of the death of Mr. Lewis Morris Rutherfurd, which took place at his country home, "Tranquillity," New Jersey, on May 30th.

Mr. Rutherfurd, says Mr. O. G. Mason, in the course of a biographical notice of the deceased man of science which appears in a recent number of the *Photographic Times*, was born at Morrisania, New York, on November 25th, 1816. His father's family can be traced back through its Scotch descent more than seven hundred years. His mother was a direct descendant of Lewis Morris, one of the signers of the Declaration of American Independence. In his early years Mr. Rutherfurd gave proof of that peculiar feature of descent which physiologists have long observed, namely, the inheritance of traits of character belonging to members of the family two or three generations earlier in its history.

At the age of fifteen his education was such as to enable him to enter the Sophomore Class at Williams College, where he graduated, in 1834, at the age of eighteen. While at college his love for investigation was so intense that he became assistant to the professor of chemistry and physics in the preparation of lectures before the class, making many pieces of apparatus for their illustration with his own hands. In his early college days Mr. Rutherfurd took his first steps in the field of Astronomy. Finding among the unused apparatus of the college laboratory the disjointed remains of an old telescope, he reconstructed the missing parts and put the whole into working order. While engaged in study, and later in the practice of his profession, his leisure hours—or what would be termed such to others—were by him fully occupied in the embodiment of some chemical or mechanical device for the furtherance of his favourite science.

In the early days of his professional life, he married Miss Margaret Stuyvesant Chanler, a niece of Peter G. Stuyvesant. His wife's fortune added to his own ample inheritance was such as to permit the abandonment of his profession and the devotion of his entire time to travel and study. In 1849 he went to Europe, where he remained several years. During this visit, he met and studied with Professor Amici, the famous Italian optician, from whom he, doubtless, learned many fine points in optical work, especially in connection with the microscope, which served so well his purpose in later years.

After his return from Europe he constructed upon the lawn of his residence at Eleventh Street and Second Avenue—what was then the finest and best equipped private astronomical observatory in the country; here in the early sixties he made with his own hands for his great equatorial refracting telescope a lens of thirteen inches aperture, corrected especially for celestial photography; this lens, worked out upon his own formula and the first of the kind ever constructed, was a wonder to the astronomical world, and has since created a revolution in the methods of observation. His photographs of the moon, planets and star clusters, made with this instrument, have not yet been excelled.

At about this time he began his work upon the spectra of celestial bodies; not being able to find instruments suited to his use, he equipped—with his own and the best tools procurable—a shop in his residence, where he constructed some of the finest apparatus known to science. Many of these inventions of his active mind have served as models in the leading observatories of our own and foreign lands. Early recognising the advantages to be gained by the use of diffraction grating of finely ruled lines upon glass and metal, instead of a long train of prisms for the decomposition of light in spectra study, and learning that only small imperfect gratings made by Nobert—who kept his process a profound secret—were procurable, Mr. Rutherfurd invented and constructed a ruling engine, upon which gratings were made far surpassing any others known, some of these having more than seventeen thousand lines to the inch; many of these gratings were generously presented to his fellow workers in spectrum analysis. With these gratings his great photographs—more than eleven feet long—of the solar spectrum were made. For the measurement of the distance of stars on the plates made in the great equatorial he constructed a micrometer, which has proved most valuable in observatory work. The measurements made upon this instrument, filling many manuscript volumes of closely tabulated calculations, was issued from the press by Columbia College but a few days before the death of Mr. Rutherfurd, but too late for his examination. His illustrated papers, published in the *American Journal of Science*, show him to have been the first to classify the stars by their spectra. His knowledge of chemistry, optics and astronomy enabled him to devise and carry out plans worthy the high position he held in the ranks of the most learned.

In 1867 Mr. Rutherfurd was elected President of the American Photographic Society, on whose official board he had many years served as first Vice-President. During his administration the Society became the Photographic Section of the American Institute. He was never known to wear any one of the many decorations, emblems of rank, or acquirements which had been conferred upon him. All these were laid away in private receptacles of his home, and but few of his intimate friends ever knew of their existence. Some of the honours bestowed upon him, like the award of the Count Rumford medal, and the naming by special act of Congress as one of the organizers of the National Academy of Science, were too conspicuous and publicly known to be hidden away. The construction of instruments, the perfecting of processes, and the solution of problems which made the proudest works of nature write their own histories, was to him far more than the plaudits of his fellow-men. Rendering the collodion film stable under all conditions of atmospheric change, and making that film extra sensitive to the light in a telescope which produced the image of a distant planet, sharp in all its details, would alone entitle a man to lasting remembrance.

When he felt that he had reached a time for rest, his instruments of labour, the fine equipments of his observatory and the recorded results of observations covering a period of many years, were presented to Columbia College, in whose councils he had served as trustee more than the quarter of a century. During the last few years of Mr. Rutherfurd's life, impaired health prevented his taking an active part in astronomical work, but his wise council was sought and recognised as being of the greatest value. His liberality in the diffusion of the knowledge which he had gained was known and appreciated by hundreds who sought his advice.

BINOCULAR VISION AND ASTRONOMICAL PHOTOGRAPHY.

In some former articles and correspondence, published in these pages many years ago, I endeavoured to show what the principles of binocular vision involved in the appreciation of the third dimension of space or distance, as applied in photography, were, and gave some examples in illustration of then well-known stereoscopic slides, which had been produced from portions of several negatives, each of which appeared at its proper distance in space, exactly as it would had the whole of the picture been made in one operation; and, in more recent years, by other articles, treating of the possible application of the same principles to more strictly scientific purposes. In returning to the subject, I hope to offer some suggestions and describe an instrument that will be of service to astronomical photographers, to enable them to test the accuracy of their work as it proceeds with greater speed and efficiency than, perhaps, is possible at present.

As an outsider and a photographer, I have been greatly interested in the efforts of astronomers to press photography into their service, and the means adopted to compel it to be truthful. To ensure its records being possessed of this indispensable quality of truthfulness with gelatine in the question is by no means an easy task, and it strikes me that the star-charting scheme will fall very far short of what some of the more sanguine of its promoters expect. Whether the exact formula and mode of preparation of the gelatine plate to be employed for the purpose have been decided, and what sort of an article it is, I do not know; but, if it be no better in structure than some highly commended star plates which have been in my hands, there is room for improvement. These would not satisfy me, nor their producers, after the first blush and excitement of novelty had passed off. Both the thickness of the films and their granularity were alike fatal to refinement and accuracy. Apart from structure, the necessity of re-wetting the plates for the purposes of development and fixing introduce into a mass-like gelatine an element of uncertainty in the redistribution of strains and physical changes of other kinds, too delicate to be detected by ordinary observation, even when assisted by a network impression, or otherwise than by the most careful micrometrical measurements and comparisons.

In considering the matter, it occurred to me that, if some method of comparison between the negative, or a diapositive from it, with the actual or focal image of the same region in the field of the objective, between two negatives or diapositives from them, taken at the same period of time, or at intervals of six months or other period, or a comparison between one diapositive and the same region in the telescope at intervals could be made; in each case dealing with the photographed images, or photographed and aerial images, in small zones at a time to avoid confusion, the following results might be expected: In the first case, the superposition of the two elements by the eyes in the same field of view would, in accordance with the laws governing binocular sight, cause any displacement or distortion (probably occurring in patches) to at once appear as occupying another vertical plane nearer or farther away, as the point or points under observation were out of position either to the inner or outer edges of the plate undergoing test. Comparison of the second pair, if both were exactly alike, would show the stars as being in one vertical plane, any discrepancies taking up other planes, as in the previous instance. Those at intervals of six months or shorter periods might show parallax in some stars, due either to proper motion or position in space, to decide which of the two further tests would have to be applied. Any portions of such pairs of plates could be greatly magnified, the aerial images at the focus of the enlarging lenses being examined and compared under the binocular eyepieces, when all defects and displacements would in consequence become coarser and more prominent in proportion. Something similar would take place in the final instance—that of comparing the diapositive with the telescopic image at any time. A body new to the region or slight motion of any one would be shown as occupying a position apart from the remainder, apparently nearer or farther away, as the case might be. The method, therefore, includes the detection of defects in the process employed, and the possible discovery of planetary or other bodies, or that some of the smaller stars are sufficiently near to show parallax, and are small from size instead of remoteness.

It will be well to give here a few words of warning. Do not let any one imagine he is going to apply the method straight off without any preliminary cultivation of the delicate discriminating powers binocular vision confers. A course of instruction with much practice is essential, under the influence of which the eyes become extremely sensitive, and detect differences of the most refined nature. Such was my experience in the cultivation of my own sight for the duties devolving on me many years ago. It was part of my work to fix up combination slides for the stereoscope, and to both photograph and manufacture "stars" for some of the beautiful slides then favourites in the market. The home-made orbs proved vastly superior, having more sparkle than anything produced by means of the camera. As they had to be pricked in the dark-blue films with a needle at an exact distance asunder, some mechanical help was necessary. This had to be adjusted to produce "star" plates for the series of the particular scene under treatment, and was accomplished by trial and error on a waste plate till an amount of separation was found that satisfied the sight. This is the kind of schooling the eyes require if an observer would have success.

The binocular instrument for the examination and comparison of pairs of plates is of the nature of an enlarging camera box, but having a division down the centre, and a pair of rectilinear lenses of ten inches focus or so, mounted on fronts, and sliding within it, one in each half. The front of the box or boxes is fitted with carriers for the plates, one of the latter being put in position on either side of the division, in front of its respective lens. Behind are mounted a pair of telescopic or other eyepieces for viewing the aerial images enlarged, or otherwise, which the lenses have formed of the plates, or parts of the plates, in front, and suitable rackwork and fixings applied to the

whole to bring portions of the plates into the field of view, to adjust the extent of magnification or perfect the focus. An instrument of this description will be available for the comparison of photographs of spectra, or of anything else in which change is suspected, and of which two distinct exposures have been made. The vagaries of a gelatine plate could be made manifest by the same means. The pictures may be magnified to almost any extent, and, as their enlarged images are under examination in air, no disturbing elements arise to discount results, such as might be expected if the making of another photograph in the enlarged condition were necessary. To go to extremes by way of illustration, there is no reason why the two diapositives should not be thrown by a pair of lanterns on two screens at the opposite ends of a large room, and viewed as one from the centre—reflecting stereoscopic fashion—by means of an opera glass, fitted with right-angled prisms, or mirrors, at a right angle, or in any other way by which the full benefit of binocular effect may be obtained from the screen.

To compare a diapositive with the aerial image of the same region at the focus of the telescope or objective which produced it, a long box or tube fitted with a lens and carriers in a similar way to one half or side of the instrument just described, is mounted alongside of the telescope, or at right angles if more convenient, with mirror to divert the image into line. The transparency is placed at the front and sufficiently illuminated, the lens being adjusted to give an image exact size. A binocular eyepiece is then arranged to take in this image and that in the telescope, and unite them for comparison, as a pair of pictures are in the popular form of stereoscope. Such an arrangement as this creates a binocular telescope, whose eyepieces may be made to view a region from two points of a base line equivalent to the whole diameter of the earth's orbit.
